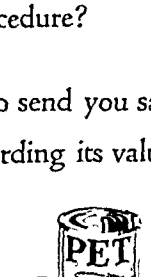
IT IS



NEVER SKIMMED MILK

In ordinary milk, as everyone knows, butterfat globules rise and form cream. In Irradiated Pet Milk these globules of fat are broken up by the process of homogenization and dispersed in tiny particles throughout the milk. So dispersed they remain in suspension, making every drop uniformly rich in butterfat as well as in the other solids of whole milk.

To appreciate more fully the overall value of Pet Milk as an aid in the treatment of digestive diseases, consider also these other qualities: Sterilized in sealed containers, it is free from micro-organisms which can cause disease or digestive disturbance—it is more readily digestible than raw or pasteurized milk—better suited to the patient who is allergically sensitive to ordinary milk—and, despite these points of superiority, it costs less generally than milk in any other form.

Since Irradiated Pet Milk possesses this unique combination of qualities, would it not be logical to prescribe it whenever milk is indicated as part of your therapeutic procedure?

We should be glad to send you samples of Irradiated Pet Milk, and additional information regarding its value in relation to the treatment of digestive diseases.

CAL-BIS-MA - CAL-BIS-MA - CAL-BIS-MA - CAL-BIS-MA

Gastric Hyperacidity

In the relief of gastric hyperacidity, *speed* is essential — Cal-Bis-Ma provides it. The neutralizing effect should be *prolonged* so as to prevent secondary acid rise—again Cal-Bis-Ma takes care of that. The irritated gastric mucosa should be soothed and protected from further irritation — that, too, is an important mission of Cal-Bis-Ma. Send for a trial supply and descriptive literature.

FOR PALATABLE DIETARY RECIPES

CONCENTRATIONS OF KNOX GELATINE

up to 10%

Knox Gelatine contains 25% of glycine, (amino-acetic acid) and is an easy, pleasant means of augmenting the diet of those persons needing this acid.

Knox Gelatine surpasses in every respect the minimum U. S. P. requirements; pH about 6.0; contains no carbohydrates; bacteriologically safe.

TO MAKE FRUIT JUICES CONTAINING 10% OF KNOX GELATINE

Place 2 envelopes of Knox Gelatine in a glass. Add 5 ounces fruit juice, orange, pineapple, grape, lemon, etc. Stir well. Dissolve over hot water. Sugar or lemon juice may be added if desired. Have the patient drink at once. Five ounces of such fruit juice drink give an *additional* 13 grams of gelatine-protein or 60 calories Two envelopes of Knox Gelatine blended with tomato juice, cereals or cooked fruit portions, give equal *additional* nourishment.

TO MAKE DESSERTS CONTAINING ABOUT 8% OF KNOX GELATINE

Any beverage can be utilized as a dessert. Usually fruit juices are used. Put 2 envelopes of Knox Gelatine in a bowl. Add 1½ ounces of cold water. Heat 5½ ounces of fruit juice and pour over soaked gelatine. Stir well until mixture is dissolved. Let stand until firm. To mold, rinse a mold in cold water and pour in the gelatine mixture. A seven ounce portion gives an *additional* 13 grams of gelatine-protein, or 60 calories.

Mail coupon today to receive these valuable, new dietary booklets.

SPEED GROWTH GAINS *with* KARO

CYCLES OF GROWTH FROM BIRTH TO MATURITY

The course of growth from birth to maturity is continuous but rhythmic. This span includes three cycles. The rapid growth in infancy is followed by the slow growth during the pre-school period; the rapid growth during the period of second dentition is followed by the slower growth during childhood; finally, the rapid growth during pubescence is followed by the slower growth during adolescence.

From Kugelmass' "Growing Superior Children", 1935. (Appleton-Century)

How MUCH should a child grow or gain from time to time? That is more significant than mere weight and height measurements. *To the parent* the mark on the wall and the reading on the scale reveal the child's growth. But *to the doctor* deviations from the periodic gains offer a sensitive index of dietary or disease disturbances.

The weight curve in infancy furnishes the most delicate index of progress. The birth weight doubles at five months and trebles at a year. Thereafter gains are slower; six pounds during the second year; five during the third; four during the fourth and fifth years. The trend of the first growth cycle is indicated in the chart.

This pattern of growth repeats itself during childhood and adolescence. Once the growth increments have been determined for a child, his assessment becomes individual and accurate.

When the child fails to gain in weight, high caloric feeding is simplified by reinforcing food with Karo Syrup. If the total caloric intake exceeds the output, the child will gain weight, provided the diet is adequate and chronic disturbances corrected. Every article of diet can be enriched with calories—Karo provides 60 calories per tablespoon. It is relished added to milk, fruit and fruit juices, vegetables, vegetable waters, cereals, breads and desserts. Karo consists of dextrins, maltose and dextrose (with a small percentage of sucrose added for flavor).

Corn Products Consulting Service for Physicians is available for further clinical information regarding Karo. Please Address: Corn Products Sales Company, Dept. DN-7, 17 Battery Pl., New York City.

MISCIBILITY *demonstrated*

The two flasks here illustrated contain an equal amount of mineral oil. The one at the right is Petrolagar emulsion and water, the other is plain mineral oil and water. • Although shaken vigorously, the plain oil and water separate immediately as shown in the accompanying illustration, whereas the oil in Petrolagar remains suspended. This demonstrates the miscibility of Petrolagar. • Since Petrolagar is miscible in water and mineral oil is not, it is obvious why Petrolagar readily mixes with the bowel contents. The oil, being in minute globules, has less tendency to leakage. Petrolagar promotes efficient, comfortable evacuation.

Petrolagar Laboratories, Inc., Chicago, Ill.

Petrolagar is a mechanical emulsion of pure liquid petrolatum (65% by volume) and agar-agar, accepted by the Council on Pharmacy and Chemistry of The American Medical Association for the treatment of constipation.

VITAMINS IN CANNED FOODS

III. VITAMIN A

• The most characteristic evidence of severe human vitamin A deficiency, and one which is increasingly rare in this country, is xerophthalmia. Night-blindness, one of the manifestations that usually precedes xerophthalmia, has been recognized as a deficiency disease since the time of Hippocrates who described the disease, and its cure by eating liver. Infrequent reports of this disorder, however, still appear in the American literature. Most if not all of the symptoms accompanying a deficiency of vitamin A are thought to be the result of an impairment of the epithelial tissue (1). In this connection, a new method for the quantitative determination of this vitamin is based on the keratinization of germinal epithelia (2).

That vitamin A exerts an influence on the growth of human infants and children is also generally accepted.

As early as 1919, a relationship between vitamin A in plant foods and plant pigments was postulated. Research since that date has indicated that beta-carotene and some related compounds may be considered as provitamin A (3).

The vitamin A potency of fruits and vegetables is apparently due to their carotene content, since vitamin A as such has never been found in plant tissue. Ingested carotene is believed to be converted into vitamin A by enzyme action in the liver of the animal (4), in which organ the vitamin is stored.

Vitamin A in the form of carotene may be present in yellow, green or red pigmented fruits and vegetables—in the two latter cases, the yellow color of carotene being masked by other pigments present. Color alone, therefore, is not always a reliable index of potential vitamin A potency.

Both vitamin A and carotene are relatively stable to heat but are subject to destruction by oxidation. However, foods of both animal and plant origin, when canned by modern methods, have been found to retain their vitamin A potencies in high degree (5).

In fact, in some instances, practically no loss of vitamin A potency can be detected by formal bio-assays (6).

Commercially canned foods, therefore, may be used with the knowledge that they will contribute to the American dietary amounts of vitamin A entirely consistent with those contained in the raw materials from which they were prepared.

"If I had my choice of only one milk.."

"What form of milk would I choose if I could have only one kind? I'd choose irradiated evaporated milk. Why? Because it possesses a combination of qualities that is found in no other kind of milk."

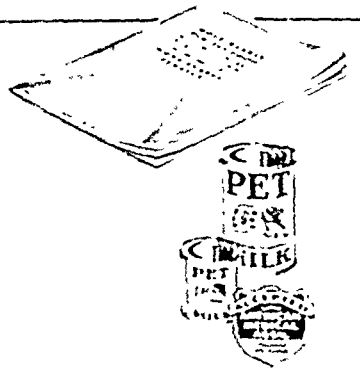
So spoke a distinguished physician. Then the question: "Why don't you use it in preference to other forms of milk?" And the answer was: "I do."

A reasonable conclusion, isn't it?

Irradiated Pet Milk possesses that superior combination of qualities...

Every drop is uniformly rich in all of the food substances that milk can be relied upon to supply.

Sterilized — it is completely and *surely* free from bacterial life — a positive safeguard against milk-borne infection.



More readily digestible than ordinary milk, it is less likely to cause intestinal irritation.

It is hypo-allergic in its effect on the patient who is hyper-sensitive to milk protein.

Irradiated with ultra-violet rays, it is richer in vitamin D than ordinary bottled milk, or ordinary evaporated milk.

It costs less generally than ordinary milk.

Since no other form of milk equals Pet Milk in this combination of virtues, is it not logically the milk to choose? Let us send you samples and literature.

Check gastric hyperacidity without the use of alkalies!

antacid ——— adsorbent

AMPHOJEL, Wyeth's Alumina Gel, is a creamy palatable colloidal suspension of 5% hydrated alumina—Al $(OH)_3$—capable of neutralizing in 1 hour not less than 12 volumes of gastric juice containing 0.36% hydrochloric acid. Thus, 4 cc. will neutralize 48 cc. of such juice or a corresponding amount of stronger secretion. It is practically free from salts (less than 0.25% chlorides) and is free-flowing and palatable, being flavored with a trace of peppermint. Amphojel lacks even the remotest tendency to bring about a secondary rise of acid secretion.

Indicated for the control of gastric hyperacidity

The FIRST SPOONFUL TO THE LAST . . .

Agarol is supplied in 6, 10 and 16 ounce bottles.

Uniformity of composition throughout is important in an emulsion. It assures uniform action from every dose. Agarol is such an emulsion of mineral oil and agar-agar with phenolphthalein. It pours freely as a good emulsion should. It mixes readily with liquids and stays mixed without "cracking."

In the relief of acute constipation and in the treatment of habitual constipation, Agarol affords proved efficiency, consistent reliability, combined with palatability that only purest ingredients can give without artificial flavoring. Let us send you a trial supply. Please ask for it on your letterhead.

Knox Gelatine

Softens Casein Curds in Artificial Feedings

"The proteins in woman's milk and in cow's milk differ both in amount and in character. In woman's milk, the proteins consist of lactalbumin and casein in the proportion of two-thirds of the former to one-third of the latter. In cow's milk about one-sixth of the protein is lactalbumin and the remainder casein. The total protein in human milk precipitates in fine flakes, that of cow's milk in heavy curds."

Friedenwald and Ruhrah-
"Diet in Health and Disease"

A

B

A—Without refrigerator, Knox Gelatine makes indigestible milk curds.

B—With refrigerator, Knox Gelatine makes soft, finer-flaked milk curds.

In baby's milk formula, the danger of hard, tough, casein curds may be avoided by the addition of Gelatine (U.S.P.). The colloidal action of a pure gelatine—such as Knox—emulsifies the milk, forming fine, flaky, casein curds.

Only 1% Gelatine U.S.P. added to the daily formula will decrease milk curd tension 50%. It is recommended through research finding that one envelope of Knox Gelatine—which is equivalent to 1 level tablespoonful or ¼ ounce—added to the prescribed daily milk formula will bring desired results of soft, digestible curds.

Knox Gelatine is scientifically made from selected long, hard, shank beef-bones—surpasses minimum U.S.P. requirements—pH about 6.0—contains no carbohydrates—fat content less than 0.1%—odorless—tasteless—bacteriologically safe.

DOCTOR—when prescribing, specify Knox Gelatine to assure U.S.P. quality.

KNOX SPARKLING GELATINE

PREVAILING opinion in regard to psychic factors in the etiology of cardiospasm may be stated as follows: (1) that the disorder is a physical one and psychic factors are considered of no importance or are unnoticed; (2) that it is a disorder of physical origin in which psychic factors are frequently found which are probably secondary to the physical disorder; (3) that it is a physical disorder in which psychic factors are present because these individuals are subjects with autonomic imbalance, that is, vagotonics, in whom physical disorders of the vegetative nervous system and psychological difficulties are apt to coexist; (4) that in some way psychic factors, acting through the vegetative nervous system, are specifically responsible for the cardiospasm.

These viewpoints are not so very different from current attitudes in regard to the other numerous functional disorders of the gastro-intestinal tract, and indeed, for our purposes, cardiospasm may be said to constitute only one small phase of this larger problem which is so badly in need of solution. The question of cardiospasm may be said to have an even greater implication, in that it touches upon the great border-line problem of the interrelationship of physical and psychological disease. For if evidence were forthcoming in favor of the psychogenic origin of even some cases of cardiospasm it would aid in the establishment of the important concept of the role of psychogenesis in the determination of structural disease, a field of medical investigation that is just beginning to be studied.

In order to develop this point let me suggest that the concept of disease bequeathed to us by nineteenth century medicine could be expressed in the following formula:

cellular disease — structural alteration — functional (physiological) disturbance.

The development of this concept represented an about-face from the medical ideas of the period of the priest—physician who was especially concerned with the spiritual basis of illness. With the introduction of the structural concept of disease by Virchow there occurred a separation of illness from the *psyche* of man and a consideration of disease as only a disorder of organs and cells. With this separation of disease into many different ailments came the development of specialists to attend to all of these distinct diseases. With the specialist came the introduction of instruments of precision and the mechanization of medicine began. Medicine then contented itself with the study of the organism as a physiological mechanism, impressed by blood chemistry, electrocardiography, etc., but unimpressed and, indeed, often holding in contempt the psychological background of the individual which was not considered as scientific as the result of laboratory studies. This period may, in truth, be referred to as the "machine age in medicine." It is not to be denied that remarkable developments have occurred during this period of laboratory ascendency but it also must be admitted that the emotional side of illness has been almost entirely neglected. As a consequence there has been a lack of insight into the emotional problems and accompanying organ dysfunctions of the sick individual.

Since the turn of the century, however, physicians have begun to recognize that cellular disease may be preceded by long-continued functional disturbance: witness, for example, the development of this conception, during this period, in regard to the disorder of essential hypertension and vascular disease. Under certain circumstances, therefore, the formula of disease could then be altered to read:

functional disturbance — cellular disease — structural alteration.

We are still in the dark as to what may precede the functional disturbance, as in the example just cited of essential hypertension and resulting vascular disease. May it not be that future investigations will permit us, in some cases at least, to say that it is possible, among other causes, for a psychological disturbance to antedate the functional alteration. Then, in some instances, the formula would read:

psychological disturbance — functional impairment — cellular disease — structural alteration.

I do not think it is necessary to point out that psychic factors, acting through the vegetative nervous system, can affect the function of various parts of the gastro-intestinal tract. Cannon, in his noteworthy experiments, proved that point many years ago and we have familiar daily examples of vomiting, diarrhea,

*Presented, by Title, at the 38th Annual Session of the American Gastro-enterological Association, Atlantic City, N. J., June 10-11, 1935.

†Professor of Clinical Medicine, Temple University School of Medicine.

etc., directly traceable to forceful emotional influences. What is not so generally accepted, however, is that long continued (chronic) disturbances of a physiologic nature can also be due to psychological influences. The very fact that these powerful psychological influences are of *unconscious origin* explains their persistent effect and also the fact that they are not well understood generally.

The present study is not concerned with the pathogenesis of cardiospasm. Nor does it pretend to be an exhaustive psychological study. It is only an effort to enter a little more thoroughly into the emotional lives of patients with cardiospasm, than previously reported cases indicates has been done, in an attempt to see if some meaning for the disorder can be found from the standpoint of behavior.

The following cases have been selected from a group referred to me for general medical study through the kindness of Dr. C. L. Jackson of the Bronchoscopic department, Temple University Hospital. His own views on the subject have been published recently (1).

AUTHOR'S STUDIES

Case I. An unmarried school teacher, aged 30, complained of stomach trouble and swallowing difficulty, of about 6 months' duration. She always had been constipated but had had no previous serious illness. She had lost 28 pounds since the onset of the present illness. Other than the poor nutrition, physical examination was negative. Esophagoscopy and X-ray showed cardiospasm but no dilatation of the esophagus. In treating the patient Dr. C. L. Jackson found that she did not tolerate the dilator well but it was felt that there had been some response to dilatation and *the patient wanted treatment.*

LIFE SITUATION

The patient was a middle child in a large family the medical history of which threw no light on the patient's illness. The family is described as a religious one and two sisters married ministers. The patient states that she was a normal child; that she had had no behavior difficulties except an occasional nightmare.

Menses was established at 14; periods were always regular and never associated with pain until recently. She attended normal school and college, fitting herself as a teacher. She then obtained a position as a high school teacher in another city and developed many cultural interests in addition to her teaching. She was a very industrious person seeking constantly to improve herself and widen her outlook.

She was not interested in boys, nor did she develop any such interest until she went to college. She grew up with the idea that it was improper for parents to have intercourse except for the purpose of having a family.

Several years ago she began to receive attentions from another teacher in the school, a man thirteen years her senior, who had separated from his wife and was about to obtain a divorce. Even before his divorce was granted, he suggested marriage but her family objected. This took place in the summer three years ago and she recalls that she suffered some indigestion coincident with the receipt of the letter from her family objecting to the proposal. Subsequently he frequently suggested marriage but for one reason or another she has held off. The reasons stated by the patient do not seem satisfactory for this long postponement of marriage. During this period her suitor was persuading her to have intercourse on the basis that it was a necessary test for marriage. The patient had no sexual desire and had many moral scruples against intercourse. However, she gradually overcame them and finally submitted but with great fear of becoming pregnant. About the same time she developed dysmenorrhea and had one rather severely painful period. She also noted an increasing irritability. A menstrual period began on February 8, 1933, but stopped two days later and she promptly considered herself pregnant and with this a severe attack of indigestion began. The indigestion was immediately followed by difficulty in swallowing. She entered a hospital and remained about three weeks without benefit. So great was her fear that in spite of the fact that her menses returned she continued to believe herself pregnant, suffered from morning nausea and vomiting and stated that her abdomen was swollen and hard "just as though there was a baby inside." In April her physician stated that he would have to make a gynecologic examination and this exaggerated her fear of pregnancy. He did not do so, however, and gradually her fear left. During this whole period she had many arguments with her suitor and at times felt that she would lose him and this, of course, added to the humilation of the supposed pregnancy. On one occasion he was supposed to visit her but wrote saying that he would have to postpone his visit. Immediately she had an exacerbation of her swallowing trouble. And it was just following this episode that Dr. C. L. Jackson reported, after an attempted treatment, "the esophagus failed to relax; the crico-pharyngeal pinch-cock was tightly closed. The patient does not tolerate the dilator well." Now, in addition, each menstrual period was associated with an increase in swallowing trouble.

The picture we get is that of a sexually inhibited (frigid) girl who had great difficulty in bringing herself to marry, maintaining a long engagement, finally yielding to intercourse, probably persuaded by the threat of losing her man whom she was afraid to marry and afraid to lose. Finally her guilty feelings culminated in an ill-founded idea that she was pregnant, because of a disturbance in her menstrual period, and then indigestion and swallowing difficulty occurred and presisted. So exaggerated was her fear of pregnancy that it was maintained in spite of subsequent menstrual periods, and thus we obtain some insight to the degree of fear and how powerful its influence might be in affecting the functions of her body.

In this case, therefore, cardiospasm occurred in a young woman with repressed sexuality in whom an obvious and easily ascertained conflict over marriage and sexual transgression seemed to act as the precipitating factor.

It is not at all unusual for young women to influence their menstrual periods by emotional disturbances arising in connection with the idea of pregnancy, but it is unusual for the fear and guilty feelings to be as pronounced as in this patient. This could only occur in a person with pronounced sexual inhibitions. Apparently this sexual transgression, which would not have provoked such symptoms in an average girl, called for an unusual degree of self-punishment in this patient.

It might be stated at this point that disturbance in sexuality is not the cause of neurosis but simply serves

as an index to a neurotic personality. There has been much misunderstanding on this question. In personality study sexual difficulties, such as impotence and premature ejaculation in the male and frigidity of various degrees in the female, serve as clues to the kind of a personality that is very liable to develop a neurosis. They, themselves, are not the cause of the neurotic difficulty.

In the next patient the problem was not quite so obvious and called for more insight into unconscious mental forces so that the conflict, of which the patient was unaware, could be detected.

Case II. A white girl of 19, was first seen in July, 1933. The cardiospasm, with evidence of some esophageal dilatation, was of three years duration. The previous medical history did not seem important in relation to the cardiospasm.

LIFE SITUATION

The patient described herself as a spoiled child (because she was an only child until the age of 12), who suffered from temper tantrums but did well in school. She is devoted to her father but does not get along well with her mother who, she says, possesses a bad temper. She is strongly under the influence of her very religious father who has had difficulty in declaring his allegiance to any one church because of his failure to find complete satisfaction there. At the age of ten she was sent to the Sunday School of the religious organization to which her father became a new adherent. She can recall even at this early age attending a revival meeting and subsequently having religious doubts about her own "feelings." Already she possessed the ambition to come a missionary. All through high school she had grave doubts of a religious nature. Then, during her senior year she was unable to decide what college to attend. She wanted to go to some "modern" school but feared that it would possess a "jazz" spirit and this was at variance with her religious belief which was, to forsake worldly pleasures, such as dancing, cards and the theatre.

About this time her father brought her difficulties to a climax by talking to her "on the necessity of becoming a true Christian—she had become old enough, 16." She was terror stricken by her father's conclusion and pretended, by reading a book, that she did not hear what he was saying. It was at this time that her swallowing difficulty first appeared.

She finally chose a conservative college but while there a very severe attack of swallowing difficulty occurred in connection with the idea of engaging in college dramatics to which she had been very devoted. Her reason was rather fanciful but none the less valid (as easily was apparent from her attitude in our discussion) that is, she feared that if she became successful in dramatics it would offer her the additional temptation of a successful stage career. And so she thought "I cannot take a chance on becoming a dramatic success, then I could not be a Christian." The situation was the same as before, that is, a conflict between freedom and the straight and narrow path of her (and her father's) religious beliefs.

In this case cardiospasm arose in a girl with a pronounced emotional conflict over the question of religion. The swallowing difficulty occurred when the conflict was at its height and was exacerbated when further psychic situations touched her emotional problem. She told me that shortly after she developed the illness she thought that she could resign herself to it "because it was intended by the Lord." She looked upon the illness as something outside of herself, for which she was in no way responsible, and felt quite hopeless about treatment. She thought the disorder would disappear "when He willed it so." She was very touchy on this religious question and resented any implication that a conflict existed in her and that her swallowing difficulty was the answer to that conflict. For it would seem that the symptom served several purposes. As she, herself, expressed it "it served the useful purpose of keeping her away from a 'jazz' school and led her into the proper path of the true religious faith." At the same time it was a protest against the harshness of this straight and narrow path and was also the inner revolt of a mild and passive creature against the father's religious fanaticism. More than that it punished her for thoughts of digression but, at the same time, succeeded in evoking her father's sympathy, whose devotion she so much desired.

The father, too, considered his daughter's condition "beyond human help." Nevertheless, he continued to send her for treatment and constantly sought advice and opinion regarding her condition.

It also must be apparent, from her resigned attitude toward the illness and the purposes that it seemed to serve, that mechanical treatment alone could hardly hope for success. Indeed, so necessary did the illness appear to be for a partially satisfactory adjustment of her emotional life that to take it away without preparing her psychologically might have resulted in its being replaced by a more serious condition, as apparently happened in another case.

In passing, it might be remarked that the religious question has frequently served to focus anxiety and thus precipitate a neurotic illness in adolescents who have neurotic tendencies.

Case III.* A white man of 55, first seen in February, 1933, showed marked cardiospasm and pronounced esophageal dilatation.

The patient gave the usual medical history of this condition. He stated that his illness began about 8 or 10 years before and had become progressive. He had consulted many physicians. Discouraged, he had invested a large sum of money with an osteopath who had promised cure. Finally, when very sick and without funds he had come to the hospital. The previous medical history did not seem to bear upon this illness.

LIFE SITUATION

The patient had been "born into the drug business" and had never known anything except the long hours and tedious work of an under-paid pharmacy clerk. He married young and five children came in rapid succession. It was a great financial struggle to look after them. About 1916 or 17 while working very hard he had "some kind of a nervous breakdown" which lasted several weeks. In 1922 his oldest and favorite son, then age 20, had just obtained an excellent job which paid well. He gave his salary to his mother and the father was overjoyed with the finally achieved prospects of economic freedom. He had always pictured a great career for this able son and had looked forward to his financial aid in old age.

Without warning one morning shortly afterward he

*Previously published (2) as one of the cases illustrating the necessity for personality study in the practice of internal medicine.

learned that this son had secretely married. He said "It was the greatest blow I ever received, not only because of the financial part of it but the way he did it." The patient placed his hand in his epigastrium to show where he had felt the blow.

He could not get over this disappointment and even considered having the marriage annulled on the basis that the boy was too young to marry. It is interesting to note, however, that he, himself, had married at the same age. He harbored a great deal of resentment for the girl's parents who, he felt, had stolen his fine son from him. It was during this period that attacks of swallowing difficulty occurred and grew more pronounced and more frequent.

A short time later further aggravation occurred. He learned that his brother in England, whom he described as a ne'er-do-well, was cheating his mother of her small legacy. He went to England, brought his mother back and she now makes her home with him. It is significant that the mother contributes her whole income to the up-keep of him and his family. In other words, while he accuses his brother of having "bled his mother" he, himself, had already borrowed money from her and now takes her weekly allowance for living expenses. His altruism in rescuing her from his ne'er-do-well brother seems questionable.

The picture we get is that of a meek, submissive and dependent individual who had always worked hard without achieving success, strongly identified with his oldest son in whom he hoped to achieve the success denied himself. With his son's secret marriage came a tremendous disappointment from which he could not recover.

An interesting commentary in line with my thesis is his experience with the osteopath. He consulted him about December, 1931, and was charged $1,000 "for the management of his case," which his sons had to borrow. It is interesting to consider why he felt like investing this great sum of money with the osteopath. He says "the osteopath told me that my trouble was due to a spasm arising from a shock" and the patient went on to say to me "he did not know about my son's marriage." He was much impressed by this diagnosis "because it was the first time that any doctor had suggested that shock and worry might be responsible for my trouble." He thereupon placed his entire confidence and all the money that he could raise in the osteopath's hands.

In the recital to me, accompanied by great emotion, this poor druggist made the following significant and perhaps revealing statement. "My son's marriage was a bitter pill that I could not swallow." And who can say that that was not, at least, one meaning of the illness?

For it would seem, from the resentment with which he speaks of his son's "treachery," that the aggression which this meek and dependent creature would like to express against his son, but cannot because of his attachment to him, is turned against himself. However, it is interesting to observe, as frequently happens in neurotic individuals, that this illness does accomplish the purpose of making him dependent upon his son (and mother) as he had been in phantasy. And thus, he actually punishes them as well as himself.

The fourth case has a deep psychic conflict with pronounced evidences of physiological disturbance in more than one system.

Case IV. A young white man of thirty, first seen in July, 1933, complained of difficulty in swallowing and vasomotor rhinitis. Esophagoscopy and X-ray showed pronounced cardiospasm with a greatly dilated esophagus. The swallowing difficulties had begun many years before (in puberty) and had continued intermittently for several years with a severe attack about the age of seventeen. In recent years his difficulties have been very persistent.

LIFE SITUATION

The patient was an only child who describes his father as a quiet, plain person, much older than the patient's very excitable mother. The parents never got along well and separated for a period when the patient was about six years old.

His earliest recollections of himself concern attacks of fever as a child, the mother taking his rectal temperature and frequently annoying him by putting her fingers down the back of his neck to test the temperature. He also states that he had a nervous habit of chewing the pages of the books that he read.

About the age of 14 while travelling with his mother she gave him an apple, a piece of which he had difficulty in swallowing. He asked for a drink and she said, "why do you pretend that you cannot swallow the apple when you only want a drink." This attitude of her's he considered very characteristic. And his reaction to his mother has constantly been an antagonistic one. He considers his mother "a neurotic who had temper tantrums and took them out on me." He recalls that riding on the train at about this time aggravated his swallowing symptoms. At 17 he went away to school where he was very unhappy. He had a nervous breakdown and was in a sanitarium for 5 weeks. His mother then came to spend a vacation with him and they went to a high altitude together after a bad night of travel. According to the patient there was a combination of fatigue, mental depression, the high altitude and the presence of his mother. And all together he holds them responsible for a severe attack of swallowing difficulty, so that he could not get any food or even liquid down. He was rushed to a nearby city where X-ray studies were made and a diagnosis of esophageal obstruction established. From then on various treatments were attempted directed to his esophagus—gastric lavage, passing of sounds and exhibition of atropin.

Frequently during his early years he suffered from what he called bronchitis and then in 1931 the attacks seemed to be replaced by vasomotor rhinitis.

During his adolescence he was constantly disturbed by sexual worries of one nature or another (masturbation) (and on two occasions homosexual experiences) and at about the age of 24 attempted intercourse with an older woman but suffered premature ejaculation. After frequent attempts of intercourse and constant failure he consulted a genito-urinary specialist who treated him by massage of his prostate and the insertion of sounds. He constantly broods about his sexual life and gives the impression that his whole life, from puberty on, has been devoted to the purpose of accomplishing sexual intercourse successfully. Relatively speaking he seems little concerned about his esophagus. What does tremendously concern him is his impotence which he speaks of as his "sexual weakness." So profoundly is he affected that he has little energy left for his job and performs routine duties in

a very perfunctory way. He seems as little concerned about the job as he is about his esophagus. The life-long disturbed relationship to the mother, the difficulties in the sexual sphere, the lack of ambition in his job despite a good intelligence, and his unhealthy relationship to men in general are certain indications of a neurotic personality.

The conflict thus is seen to be of deeply rooted origin and seems to manifest itself in several different systems, respiratory (vasomotor rhinitis), gastro-intestinal (cardiospasm) and genital (impotence) as well as in the total personality. The specific psychic meaning of the various physical disorders is not clear but it must be apparent that to treat the cardiospasm simply by mechanical dilatation would be just as short of complete medical management as was the passing of sounds in the treatment of the impotence.

In the last case the emotional conflict became apparent only through a chance discovery.

Case V. A white girl, aged 15, had swallowing difficulty which began about a year and a half ago. Just prior to this she had had some dental work done and complained of a curious sensation of the teeth which also preceded the attack of swallowing difficulty. The attacks are accompanied by pain in the chest and salivation. Esophagoscopy and X-ray demonstrate cardiospasm with dilatation of the esophagus.

LIFE SITUATION

The patient, the youngest child of a family of five, was always in good health until the present trouble began. She suffered from enuresis as an infant and also from night terrors, and formerly was afraid of the dark, imagining a burglar to be in the house. Menses began a year before the onset of the trouble and were always regular. Frequent conversation failed to bring out any emotional occurrences that seemed significant in regard to her trouble. It is true that the financial situation was bad at home and that the mother was at times ill but neither situation seemed important in relationship to her illness. She gave the impression in her frequent interviews of being a very straight-laced young lady, interested in boys but very mindful of the dangerous possibilities of being associated with them and determined to protect herself. After many efforts to discover the cause of her trouble, quite by accident her mother came to me suffering from a functional gastro-intestinal disorder and told a story which probably had to do with her own illness as well as with the patient of whom I am speaking.

The patient has a sister 12 years older than she who has been a source of great trouble to the family. At the age of 10 this sister began having difficulties at school with truancy and false reports. At 16 she ran away from home (when our patient was 4) was brought back and ran away again at 17 and this time when she returned was illegitimately pregnant and had a child which was disposed of through an agency. The patient was aware of the fact that this sister had had an illegitimate child; she had heard her mother describe it. Still later the sister married, out of her faith, had another child and just prior to the onset of our patient's illness was being sued for divorce and had returned to her home.

It was then possible to correlate this story with the swallowing problem of our patient who, even as a small child, was well aware of the disgrace to her family, was very much concerned that nobody in the neighborhood should know of the trouble, and whose swallowing difficulty began about the time that she learned of the divorce action. A divorce, of course, meant that the bad sister would be thrown upon their hands again and endanger their prestige in the neighborhood. This coincided with the period of puberty, when, because of tremendous psycho-physical development, emotional disturbances and their physical consequences are most apt to arise. The whole situation certainly would appear to have something to do with the severe repression of our patient. She, herself, says that her sister's trouble was due to bad companions. In this connection a dream of our patient is interesting: "she was standing between two girls who fell down and blamed her." Falling down is a well known symbol for a moral fall and is over-determined in the dream. Regardless of any further meaning that the dream may have it indicates the thoughts with which the patient was concerned and from which conflict arose.

The cardiospasm apparently indicates the inability of the patient "to swallow" the family disgrace. It must be emphasized that no conscious worries could be ascertained by the simple question, "are you worried about anything?" Indeed, if the mother had not given me the story of the older daughter I do not think that, in the time at my disposal, I could have worked out this girl's important problem.

DISCUSSION

In these cases of cardiospasm, and others that I have studied, the disorder seems to have a special meaning in terms of behavior. This meaning can be discovered by a study of the personality in relation to the environment. The cardiospasm often is found to arise coincidently with an emotional conflict, in many instances during puberty, in an individual whose early life gives evidence of personality difficulties. At first the disorder frequently seems to manifest itself intermittently; later on, it may become persistently established. Exacerbations occur which, frequently, can be correlated with fresh psychic insults touching the particular complex of the individual.

In this respect, it is worthy of comment, that one may note in papers on cardiospasm statements such as "the patient did not look neurotic" or "the patient wasn't worried about anything." Unfortunately for us, most such patients do not betray their neuroses by their appearance nor is the simple question "are you worried about anything?" likely to produce material of importance. In some instances (as in Case I) the conflict is fairly obvious but in others insight into unconscious mental mechanisms is necessary in order to discover a deep conflict of which the patient may be totally unaware.

It would seem then, as stated above, that the cases cited correspond in all respects to conversion hysteria of a form deeply rooted in the unconscious mental life of the individual. The physical disorder represents symbolically the unconscious conflict—it appears to be a compromise between the gratification of certain forbidden impulses and their rejection by another part of the personality. An important meaning of the disorder often can be stated in such simple terms as "I can't swallow that (situation)." Therefore, this meaning often can be discovered by looking (psychologically) for the situation that the individual "cannot swallow."

This kind of information furnishes a specific back-

ground for the cardiospasm and replaces the loose terminology and loose thinking behind such terms as "nervous factors" and "neurogenic background" with a more exact definition of the specific psychic situation. Indeed, to speak of "nervous factors" in the back-ground of the patient with cardiospasm without further defining them seems to me as obsolete as blaming malaria on marsh gas with failure to note the part played by the malarial parasite. In self-criticism, I may say that I have not found the parasite but I do think that I have the mosquito.

I must emphasize that I do not believe that the psychic situation is the only one of importance in these cases of cardiospasm. The physiological mechanism of cardiospasm has not been discussed nor has any consideration been given to the question of the differentiation between intermittent and persistent forms with dilatation of the esophagus. Thieding (3), Vinson (4) and others make this differentiation but I did not concern myself with the question at this time. I must content myself, for the present, with the observation that psychologically, in my experiences, both have arisen out of similar situations. Nor have I discussed esophagitis in association with cardiospasm. Is it, as Lyon (5), and others have suggested, a result of the purely functional lesion that, once established, predisposes to further spasm? From the psychic standpoint, other questions have not been discussed. Why should the psychic situation affect the gastro-intestinal tract, and that particular portion of it, and why should the situation produce the illness in certain people and not in others? These are some of the questions upon which one could speculate but I prefer to await further physical and psychological studies aimed at the deeper levels of the personality and having to do with a more complete study of unconscious mental forces, only hints of which are contained in this report. Such studies would necessitate the psychoanalytic method., the application of which to the problem of the organ neuroses is a vast subject the surface of which, as yet, has only been scratched.

Whatever one believes regarding the etiological role of these mental forces, it must be apparent that to study patients with cardiospasm simply as physiological mechanisms and treat them by mechanical measures, without making some effort to understand the emotional make-up, is a very one-sided and inadequate attempt to deal with the disorder. The above observations suggest the necessity for a combined physical and psychological study and treatment of the individual patient with cardiospasm. No one can deny the necessity for mechanical treatments in the established case of cardiospasm but is it not possible that this additional psychic approach will help us deal with that group of cases "which tends to recur" or that group "which cannot be cured." Especially in regard to these groups we must consider the frequent observation that in a patient with a severe neurosis a physical disorder (such as cardiospasm) appears to be that patient's solution of his psychic conflict. The physical disorder, therefore, is necessary to the emotional life and until the psychic conflict is better solved, the particular disorder from which the patient suffers either must be maintained or must be replaced by another illness. Certainly, in an early case of cardiospasm, especially in a young person, psychologic study and treatment seem to me an essential part of the management. Indeed, I venture to suggest that the time is approaching when the physician will consider the neglect of psychological study just as serious an omission, in the total study of the patient with cardiospasm, as the failure to X-ray such a patient or study him with the esophagoscope.

Epigastric Percussion in Peptic Ulcer*

By

JACOB MEYER, M.D.

and

J. S. GOLDEN, M.D.

CHICAGO, ILLINOIS

THE paucity of definite physical signs in patients with uncomplicated peptic ulcer is well known. The tendency to seek laboratory confirmation of the diagnosis of peptic ulcer by the use of the X-ray and test meals has tended in no small measure to an almost complete neglect of a clinical sign which, in the past, has been considered a valuable diagnostic aid.

In 1903 Mendel (1) published an article entitled, *"The Direct Percussion of the Epigastrium,"* calling attention to the localization of pain to the epigastrium by gentle percussion with a reflex hammer in patients with peptic ulcer. Boas (2) in speaking of this sign

*From the Stomach Study Group, Michael Reese Hospital and the Medical Service, Cook County Hospital.
Submitted September 18, 1935.

says, "that he elicits a pain response by a reflex hammer percussion much more definitely than by finger percussion or pressure." Boas' sign is a pain elicited by percussion to the left or less commonly to the right of the 10th-12th dorsal vertebrae and is not to be confused with the Mendel test. The chief objection to the Mendel test is that pain may be elicited from various points over the abdomen in a sensitive or hypersensitive patient who has no organic disease. It occurred to one of us that Libman's (3) styloid pressure test could be used to determine the degree of sensitivity in conjunction with the Mendel test. Crohn (4) has suggested a similar procedure in estimating epigastric tenderness to pressure.

For a number of years one of us has been impressed with the clinical importance of the test as described by Mendel and has employed it with the following modification. The Mendel test is first performed by gentle percussion with a reflex hammer (with a triangular rubber head) over the abdomen, employing rapid and short strokes. The epigastrium is gradually approached. In *positive* cases, pain is definitely elicited and localized to a small area either over the mid-epigastrium or 1 to 2 cm. to the right of the mid-line. The patient will react by wincing or by actually pointing to the local area of pain or tenderness. In *negative* cases, the patient will either fail to wince or will point to many areas of pain. Immediately following the percussion of the abdomen the sensitivity of the patient to pain is determined by Libman's styloid pressure method. Libman determined the sensitivity of patients to pain by pressing over the styloid processes. He divides patients into two major groups, sensitive and hyposensitive. He considers patients sensitive (+++ sensitive) if they give evidence of marked pain or admit that the test is definitely painful. Hyposensitive patients either give no evidence of pain and state that they feel none (0 — sensitive) or give evidence of little pain and admit, on questioning, that some pain is felt (+ — sensitive). Using this method as a control of the sensitivity of the individual we have been able to evaluate in a more definite manner the Mendel percussion test. Thus it becomes apparent that a positive pain localization by percussion of the epigastrium in an hyposensitive patient is of diagnostic value in patients with peptic ulcer.

TABLE I

Patients With Ulcer Story

X-ray	Number	Positive Response to Percussion Test	Hyposensitive	Sensitive
Ulcer Defect	48	36	33	3
No Ulcer Defect	14	4	4	0
Total	62			

The X-ray examination, abdominal percussion and *sensitivity to pain (Table I) were studied in sixty-two* patients with a history typical or suggestive of peptic ulcer. Fluroscopic examination revealed an ulcer defect in forty-eight patients, thirty-six of whom exhibited a positive reaction to pain on percussion of a localized area in the mid-epigastrium or slightly to the right of the mid-line. The styloid pressure test demonstrated that thirty-three of the thirty-six patients were hyposensitive.

Of the fourteen patients without a demonstrable ulcer defect, four exhibited a positive pain reaction on epigastric percussion. All of the four were found to be hyposensitive. It is of interest to note that subsequent fluroscopic examination of one of these four patients revealed an ulcer defect which disappeared on ulcer management. Another had several hemorrhages from the upper gastro-intestinal tract *during the following three years though at no time* did X-ray reveal an ulcer.

Forty-three patients without an ulcer history but suffering from various diseases (arthritis, diabetes mellitus, etc.) were studied as to the reaction to abdominal percussion and sensitivity to pain. No X-ray studies were made. A positive pain response on percussion was elicited in six. All but two of the entire groups were hyposensitive. (Table II).

TABLE II

Patients Without Ulcer Story

Number	Positive Response to Percussion Test	Hypersensitive	Sensitive
43	6	42	1

In five patients with cholelithiasis a positive response to percussion was elicited, but the area of tenderness was larger and located over the right upper quadrant. All were hyposensitive according to Libman's test.

SUMMARY

We direct attention to the gentle percussion with a reflex hammer of the epigastrium in patients with peptic ulcer as a diagnostic aid and suggest it be controlled by Libman's test for pain sensitivity.

Our experience indicates this modification of the Mendel test as valuable in the presence of a typical history of peptic ulcer.

With an atypical history, the determination of localized epigastric tenderness by gentle percussion suggests peptic ulcer. This is made more certain if the patient is hyposensitive.

In an hyposensitive patient with a typical ulcer history but in whom an ulcer defect is not demonstrated, the Mendel percussion test is of diagnostic value.

On the Anemia Following Gastric Operations

By

HELGE LUBLIN, M.L.

STOCKHOLM, SWEDEN

A NUMBER of comprehensive clinical investigations (1-16) have indicated that post-operative anemia is a relatively common finding after gastro-enterostomy or gastric resection. A large number of authors have described isolated cases of either pernicious anemia or a "grave anemia" following gastro-enterostomy or extensive gastrict resection (17-22, and numerous others during the past decade) after various intervals of time. These cases now number about two hundred. Further, hypochromic anemia has been produced experimentally by means of total gastrectomy in dogs (23-28, 6), rats (29-31) and pigs (32, 33). However, a hyperchromic post-operative anemia has not been successfully provoked, and it is well known that in man post-operative hyperchromic anemia is comparatively rare, while the hypochromic form is relatively common.

When the anemia appears many years after the operation it is natural to consider it independent of the operation. Of course, it is also necessary to exclude those cases, in so far as is possible, in which pathological processes existing prior to or after the operation may account for the anemia.

It is believed that post-operative anemia is more extensive than is generally recognized, because several factors operate in ordinary clinical practice to hide its incidence. As Gordon-Taylor (3) has pointed out, the patients are often only slightly, or not at all, troubled by the anemia and do not consult a physician, and the anemia is not discovered by the questionnaire method which is so commonly employed for post-operative examination. If exact figures of the incidence of post-operative anemia are to be obtained, the patient's blood must be examined, a procedure which is frequently beset with practical difficulties. Recently, however, a few such studies have been made (2, 3, 7, 8, 9, 12, 13), from which material a frequency of from 25 to 50 per cent has been obtained.

The author cannot present such a frequency figure, because the source of his data is different, but nevertheless instructive. My data comes from a study of those patients which were secondarily treated in the medical department for non-hemorrhagic post-operative complaints. As early as 1931, after a study of such patients in the Seraphim Hospital between the years 1919 and 1928, the author expressed the decided opinion that the occurrence of post-operative anemia following operations on the stomach is relatively common (4). Although the patients most commonly had a hypochromic anemia, several had a hyperchromic anemia with the typical blood picture of pernicious anemia. Since 1928 the author has continued to study similar patients, which were kindly placed at his disposal by the respective heads of the medical departments at the Sabbatsberg Hospital in Stockholm.

Submitted October 15, 1935.

OBSERVATIONS

The results of this latter study are briefly summarized in Tables I and II. It is to be noted that blood studies were made on forty-six patients. Twelve of the twenty-six males had a "mild" anemia and three a "well-marked" anemia. Eight of the female patients had a "mild" anemia and nine had a marked anemia. Or, 69 per cent of the patients suffered from anemia. Seven of the forty-six patients had been subjected to the Billroth II operation, and of these only one had a normal hemoglobin and red cell value. In the remaining thirty-nine gastro-enterostomy patients, the pyloric antrum had been resected in six. All of these had anemia.

TABLE I

Distriution of Patients With Reference to Blood Values

	Normal values	Mild anemia	Well-marked anemia	Number of examined cases
Males	11	12	3	26
Females	3	8	9	20
Sum total	14	20	12	46

TABLE II

Distribution of Patients With Reference to Operation and Blood Values

		Normal values	Mild anemia*	Well-marked anemia	Number of examined cases
Gastro-enterostomy	Males	11	10	2	23
	Females	2	4	4	10
	Total	13	14	6	33
Gastro-enterostomy with exclusio pylori	Males	0	1	1	2
	Females	0	2	2	4
	Total	0	3	3	6
Billroth II	Males	0	1	0	1
	Females	1	2	3	6
	Total	1	3	3	7
	Sum total	14	20	12	46

**Note*: "Mild anemia": In men = haemoglobin 70-80%, red blood corpuscles 4-4,9 mill. or both these values simultaneously; in women = haemoglobin 65-70%, red blood corpuscles 3.7-4.4 mill. or both these values simultaneously. Values falling below those submitted for "mild" anemia are referred to as "well-marked" anemia.

It cannot be concluded from the author's material whether anemia is more common after subtotal gastric resection than after gastro-enterostomy. Evidence bearing on this question has not been found in the literature. However, the data submitted gives the impression that resection is more likely to lead to

anemia than is gastro-enterostomy. It would appear to be quite evident that post-operative anemia is more likely to occur in women than in men.

DISCUSSION

A question of the greatest interest, which must still be considered as only partially solved, is the cause of post-operative anemia. The final solution of this difficult problem is probably also of great importance for the elucidation of the cause of certain other forms of non-post-operative anemia, which have not yet been fully investigated.

A gastric insufficiency following an operation, possibly associated with achylia, achlorhydria or hypochlorhydria as an expression of this injury, will probably prove to be the chief cause of the anemia appearing after the operation. In such cases, the anemia usually takes the form of simple achylic anemia (Faber's anemia), and more exceptionally the form of *anemia perniciosa*. In other cases, again, it must be assumed that the cause of the anemia is to be sought, at least partly, in the reduction of the size of the stomach, so-called "agastric anemia" (Morawitz, *ref.* 34). It is probable that in both these groups the cause is one and the same. Corroborative evidence of this is found not only in the well-known works of Faber (35) and his followers on the connection between achylia, achlorhydria or hypochlorhydria and different forms of anemia, but also in the pioneer investigations published during the last few years by Castle (35, 36) and his collaborators on "the intrinsic and extrinsic factor." From these works we have obtained a knowledge of the fundamental importance of the stomach and its functions as related to the occurrence and prevention of both hypochromic and hyperchromic anemia.

The *antrum pylori* appears to be the part of the stomach which is most active in producing the substance which, in healthy persons, prevents the occurrence of pernicious anemia. Henning and Brugsch (37) have made a comparative test of the antianemic effect of the mucous membrane of the fornix, fundus, antrum and duodenum. These investigators, and later Meulengracht (38), found that the mucous membrane of the antrum was the most active. It would appear that the more extensive the gastric resection, the more likely post-operative anemia will occur, or the more the patient must depend on the "intrinsic factor" in the intestine.

It is more difficult to explain the occurrence of anemia in those patients in which post-operatively the secretion of acid is found to be within the normal range. Such cases have been observed (2, 3, 4, 6) and must be taken into account, even though it must be acknowledged that post-operative anemia and achylia, achlorhydria or hypochlorhydria, usually are found together. In patients showing post-operative anemia with maintained acid production, as well as in many other cases of post-operative anemia, the cause is to be sought in the disturbances of the physiology of the digestive organs, and factors connected therewith, consequent to the operation as well as in the stomach itself. The circumstance that an exclusion of the pylorus, carried out in connection with simple gastro-enterostomy or resection (Billroth II), seems to increase the propensity to post-operative anemia (4, 9) speaks in favor of this. The tendency observed by Morley and Roberts (2) and recently by Fasiani (15) and Chiatellino (16) of the Billroth II operation to give rise to anemia to a greater extent than the Billroth I, also, points in the same direction. Further, it may be indicated in this connection that Dedichen (8) found post-operative achylia to be associated with anemia more often than non-post-operative achylia. This observation indicates that in post-operative gastric cases there must be some factor, other than achylia which predisposes to anemia. It may rationally be assumed that in some cases this factor is identical with the disturbances just referred to in the physiology of the digestive organs consequent to the operation.

How is the apparent relation between the disturbances in the physiology of the digestive organs and the anemia to be conceived? Exclusion of the pylorus, regardless of whether it is made in association with gastro-enterostomy or resection (Billroth II), prevents nourishment from following the physiological path from the stomach through the duodenum. In gastro-enterostomy, unaccompanied by exclusion of the pylorus, the passage of nourishment is more complicated, but in general the nourishment follows the direct path from the stomach into the jejunum. In the event that nourishment does not pass through the duodenum, the normal stimulation of this section of the intestine, which affects the secretion of the liver and pancreas, is absent. The result is that in such patients, the secretion of the liver and pancreas depends on the weaker and less specific stimulation from the jejunum and the ileum. In other words, the liver and pancreas are partially disconnected from the digestive system. In this connection it is of interest to point out that Strandell (39), in experiments with the injection of the liver preparation, "Heptomin," has observed a very pronounced reticulocyte response and a rapid change for the better in two grave cases of hypochromic anemia following gastro-enterostomy, one of which, with *exclusio pylori*, reacted in the same way as a case of anemia perniciosa. In neither Lublin's nor Dedichen's data could any correlation be shown between the frequency of post-operative intestinal disturbances and post-operative anemia, a circumstance which to some extent affords corroborative evidence that the cause of anemia is probably to be sought rather in the stomach, duodenum, liver, and perhaps pancreas, than in the lower intestine.

It should be of the greatest interest from the viewpoint of the cause of post-operative anemia to investigate the effect of *inter alia exclusio pylori* on animals, such as the pig, and to obtain post-operative blood examinations on patients who have undergone this operation.

SUMMARY

Blood studies have been made on forty-six patients who returned to the medical clinic for various complaints, other than hemorrhage, following either a gastro-enterostomy with and without exclusio pylori or Billroth II operation. Sixty-nine per cent of these patients had a hypochromic anemia. Six of the seven patients subjected to the Billroth II had varying grades of anemia. In six of the gastro-enterostomized the pylorus had been excluded; all had anemia. Post-operative anemia was more frequent in the females than the males. Observations bearing on the cause of anemia following operations on the stomach are discussed.

Incidence of Malignancy in Gastric Ulcer*

By

HSIAO-CH'IEN CHANG, M.D.†

PEIPING, CHINA

THE academic question of transformation of gastric ulcer into cancer has been a much disputed one. The figures quoted varied widely and as yet no definite agreement seems to have been reached. As summarized in the reviews of this subject by Cabot and Adie (1) and by Hurst and Stewart (2) malignant degeneration of gastric ulcer probably does not take place very frequently, certainly not much exceeding 5 per cent. In actual practice, the more pertinent question to the physician is, however, not how many of his gastric ulcer patients will later develop malignant disease of the stomach but rather how many already have it.

That a malignant gastric ulcer may present most or all the features of a benign one is undoubted by experienced observers. Not infrequently a carcinomatous ulcer may occur in a young individual, may be associated with a relatively long history and a normal or high gastric acidity, and on X-ray examination may reveal a comparatively small ulcer crater. In fact even the surgeon having the ulcer in hand may at times have difficulty in deciding the issue. It, therefore, behooves us to inquire into the incidence of carcinoma among cases of clinical gastric ulcer. This information is specially desirable in the immediate management of such patients as it has a direct bearing on the form of treatment to be followed.

The present communication deals with an analysis of 63 cases of gastric ulcer treated in Lane Hospital, with a view to clarifying the point in question.

Description of Cases. In the cases presented below the diagnosis of gastric ulcer was ascertained both clinically and roentgenologically. Special care was taken in reviewing the roentgen films and fluoroscopic record of each case, any one with the slightest suspicion of frank neoplasm being excluded. The writer is indebted to Dr. R. R. Newell for permission to use the roentgenological data. Lastly, only those cases in which the record fulfilled one of the required criteria are included in this study.

TABLE I

Age Distribution

Age in years	Number of cases
11-20	1
21-30	5
31-40	11
41-50	15
51-60	17
61-70	10
71-80	2
81-90	1
Unknown	1
Total	63

Forty-eight of the 63 cases occurred in the male and 13 in the female. The age varied between 13 and 82 years, the majority of the patients being in the 3rd, 4th, and 5th decades (Table I). The duration of symptoms is shown in Table II. When the patients first came under observation the gastric complaints

*From the Department of Medicine, Stanford University Medical School, San Francisco, California, U. S. A.

†On leave of absence from the Department of Medicine, Peiping Union Medical College, Peiping, China.

Submitted November 1, 1935.

had been present for one year or less in 40 per cent of the cases, and for more than five years in 33 per cent. The site of the ulcer was the pylorus in 15 cases, lesser curvature in 44 cases, and cardia in 2

TABLE II

Duration of Symptoms

Duration	Number of Cases	Percentage
1 month to 6 months	19	30.2
7 months to 12 months	6	9.5
1 to 2 years	7	11.1
2 to 3 years	3	4.8
3 to 4 years	2	3.2
4 to 5 years	4	6.3
More than 5 years	21	33.3
Unknown	1	1.6
Total	63	100.0

cases. The size of the ulcer is shown in Table III. In 20 cases the ulcer was described as of the penetrating type. Nearly half of the patients (30 cases) had six-hour retention, mostly (14 cases) amounting to less than 50 per cent of the barium meal. As regards the gastric acidity, there were 3 instances of achlorhydria, one confirmed by histamine test. Four patients had hypoacidity (highest titratable acidity of 20 c.c. 0.1

TABLE III

Size of the Ulcer

Diameter	Number of cases
Less than 1 cm.	4
1 cm.	14
2 cm.	11
3 cm.	6

Total	63

N per 100 c.c. or less after Ewald meal, or of 40 c.c. 0.1 N per 100 c.c. or less after alcohol meal or histamine injection) and 21 patients had hyperacidity (highest titratable acidity of 40 c.c. 0.1 N per 100 c.c. or more after Ewald meal, or of 100 c.c. 0.1 N per 100 c.c. or more after alcohol meal or histamine injection). In the remaining instances (26 cases) in which gastric analysis was done the acidity was normal.

Diagnostic Criteria. As has been said above, the exclusion of malignancy in cases of gastric ulcer is an extremely difficult matter. The most accurate method of diagnosis remains microscopic examination of the lesion, as by no other means can one say with certainty that an ulcer in question is of benign or malignant nature. In 16 cases of the present series this examination was made either after operation or on autopsy. Next to microscopy, careful inspection of the gross lesion seems to be a fairly reliable though not infallible means of differentiation. On the operating table the surgeon can ascertain at least the size, location, and consistency of an ulcer much more accurately than the internist or roentgenologist. It is true that surgeons do encounter difficulties at times and a diagnosis of benign ulcer based on operative data alone must rest open to some doubt. On the other hand when visible metastasis is already present it practically settles the issue in favor of malignancy. There were only four patients in this series in whom the diagnosis had to be decided by operation, two being benign and two malignant. Besides these two criteria, we have, in the remaining instances (62 cases), relied on the course of the disease for probable diagnosis. We assume that any patient who, after first coming for treatment, had lived for two years or longer with no clinical evidence of malignant disease, probably did not suffer from gastric carcinoma at the outset. This is necessarily arbitrary and certainly does not rule out malignant change of the ulcer in the future. Nevertheless it seems to be a relatively safe working basis, especially if it is borne in mind that at the time of their first visit 60 per cent of the patients had already suffered from gastric symptoms for more than one year.

In summary, our criteria of differentiation between benign and malignant gastric ulcers consist of: (1) Histological examination, (2) Operative data, and (3) Clinical course of the disease.

Of the 63 cases, two were those of gastric carcinoma, both proven by operation and clinical course combined. A third case of lymphosarcoma was diagnosed by histological examination of the ulcer after surgical removal. In a fourth case the clinical picture was very suggestive of carcinoma but the positive blood Wassermann reaction, the subsequent course, and the speedy response to anti-syphilitic treatment made the diagnosis of gastric syphilis highly probable. The details of these cases are abstracted in the case reports. The remaining 59 cases are classified as the benign ulcer in accordance with one or more of the criteria described above (Table IV). In only two cases was the diagnosis of benignancy somewhat in doubt as it was based on operative data alone. In the 46 cases in which benign ulcer was diagnosed by the clinical course, either alone or with one or more other criterion, 14 patients were followed for 2 years, 6 for 3 years, 10 for 4 years, 14 for 5 years or more and 2 for 10 years or more.

TABLE IV

How the 59 Cases of Benign Ulcer Were Diagnosed

Criteria	Number of cases
Clinical course alone	32
Microscopic examination alone	11
Microscopic examination and clinical course	1
Operation alone	2
Operation and clinical course	10
Total	59

To recapitulate, in the 63 cases of roentgenologically and clinically diagnosed gastric ulcer, malignancy was definitely present in 3 instances (2 carcinomatous and 1 lymphosarcomatous). Including a fourth questionable case in which gastric syphilis could not be ruled out, the incidence of malignancy was approximately 6.4 per cent.

DISCUSSION AND SUMMARY

The purpose of this study, in brief, was to obtain further information as to how often apparently benign

gastric ulcers are really malignant. It was assumed that if the patient showed no signs of cancer after a two year observation period the original diagnosis of simple peptic ulcer was correct. On this basis it turned out that three of 63 instances of apparently benign ulcer were really malignant or soon became so. This corresponds with current opinion that probably not more than five per cent of peptic ulcers show malignant change.

CASE REPORTS

Case 34. Lymphosarcoma—An American housewife of 45 complained of cramp-like pain in the right lower quadrant for five months. The pain radiated to the back and left costal margin. It was not related to food. Nausea and vomiting accompanied the pain. The gastric acidity was normal. X-ray revealed a large perforating ulcer on the lesser curvature of pars media of the stomach. Pylorectomy and posterior gastroenterostomy were performed. Histological examination showed a chronic ulcer with lymphosarcomatous base. No metastasis was found. The patient was living and well five years after the operation.

Comment. This case represents the ulcerative type of lymphosarcoma. The tumor was probably primary in the stomach and was not associated with generalized lymphosarcomatosis. The absence of demonstrable metastasis and surgical removal of the ulcer most likely accounted for the patient's survival at the end of five-year period.

Case 38. Carcinoma—A married woman of 52, with ulcer syndrome for 16 years, had an ulcer, measuring 1.5 cm. in diameter, on the lesser curvature, 4 cm. proximal to the pylorus. There was high gastric acidity and 30 per cent retention at the end of six hours. Having failed to improve on medical treatment the patient was operated on in August, 1931, and posterior gastroenterostomy was performed for an apparently benign ulcer. The patient had only slight symptomatic improvement. Roentgenological examination one year after the operation showed an irregular pyloric antrum and a mass in the epigastrium and exploration in January, 1934, revealed an inoperable carcinoma of the stomach.

Comment. In this case the carcinoma undoubtedly had existed in 1931, at the time of her first operation. This was suggested by the slight or absent improvement following gastro-enterostomy. It is difficult to evaluate the long history. Possibly carcinoma had developed on a previously benign ulcer. When the patient first came under observation, the picture was essentially that of gastric ulcer and no suspicion of malignancy was aroused even by the surgeon who operated on the patient the first time.

Case 53. Carcinoma—An American laborer of 53 had epigastric pain from two to three hours after meal for four years. The pain was relieved by food, soda, and vomiting. The symptoms had increased in severity for one month. The gastric acidity was normal. On X-ray examination, an irregular ulcer, 2 cm. in diameter and 1 cm. in depth, was demonstrated on the lesser curvature just above the *incisura angularis*. A greater curvature deformity was present opposite the ulcer. The ulcer was resected. Histological examination of the ulcer and regional lymph node showed no evidence of malignancy. There was, however, suspicion of metastasis in the liver and seven months after the operation a large mass was found in the epigastrium, "undoubtedly carcinomatous recurrence."

Comment. This patient most likely suffered from gastric carcinoma. It is hard to explain the negative biopsy findings but the presence of metastasis in the liver and the subsequent development made this diagnosis practically certain.

Case 64. A 43-year old American salesman had upper abdominal pain two hours after meal for ten years. No free hydrochloric acid was present in the gastric juice after injection of histamine. A large ulcer, measuring about 4 cm. in diameter, was located by X-ray examination, on the lesser curvature, 4 cm. above the *incisura angularis*. Six-hour retention amounted to 30 per cent. The blood Wassermann reaction was strongly positive. Treatment with diet and potassium iodide was instituted and on subsequent roentgenological examinations the gastric lesion showed steady improvement, no ulcer creater being discoverable ten weeks afterwards. The patient, when seen one and one-half years later, remained symptomless.

Comment. In this case the achlorhydria and the size of the ulcer pointed to malignancy. The fact that treatment with potassium iodide brought about rapid improvement would instead speak in favor of gastric syphilis. The patient's good health and freedom from gastrointestinal symptoms for many months would also seem to argue against carcinoma.

The writer wishes to express his indebtedness to Dr. A. L. Bloomfield for advice and encouragement and for permission to study the clinical records of the cases reported in this paper.

The Double Histamine Test as an Aid in the Study of Gastric Secretory Function*

By
ANDREW B. RIVERS, M.D.
ARNOLD E. OSTERBERG, Ph.D.
and
FRANCES R. VANZANT, M.D.†
ROCHESTER, MINNESOTA

AFTER the subcutaneous administration of histamine hydrochloride or histamine acid phosphate there is usually a marked increase in the secretion of the digestive juices. The recognition of this physiologic action resulted in the use of histamine as a diagnostic agent in the study of the secretory potentiality of the gastric glands.

The efficacy of histamine in provoking increased secretion of gastric juice is unquestioned. A point of

*Division of Medicine, Section on Biochemistry, Division of Biometry and Medical Statistics, The Mayo Clinic.
†Now residing in Houston, Texas.
Submitted November 4, 1935.

controversy remains, however, since it is still debated whether or not the enzyme fraction of gastric secretion is increased after the use of this drug. Some observers (Babkin, Gilman, and Cowgill), though noting the increase in the peptic activity of gastric juice following the use of histamine, assume that this is due to a washing out of the peptic glands accompanying activation of the secretion of large amounts of hydrochloric acid and other inorganic constituents of the gastric chyme. Polland, as well as Blakely and Wilkinson, on the other hand, report observations which suggest that the administration of histamine results in an increased output of pepsin. Blakely and Wilkinson furthermore stated that a second dose of histamine had on the whole a slightly less effect, although in one case only the second dose effected the increase. The concentration was either increased or decreased, more often the former. That the test has unquestioned value in differentiating an apparent from a true achylia gastrica seems now to be an established fact. It should not be assumed, however, that this is invariably true, because there are a few instances in which an Ewald test meal provokes secretion of free hydrochloric acid even when such secretion does not occur following the use of histamine.

For some time we at this Clinic have been interested in applying some principles of gastric function, which can be measured by the histamine tests, to certain of the problems incident to the etiology, chronicity and therapeusis of peptic ulceration. The only common denominator which is consistently and readily applicable to peptic lesions is that they occur in tissues bathed by the acid gastric chyme. Ultimately, the various interrelated factors important in the causation of ulcer would seem to resolve themselves mainly into two main factors: the one inherent in the ulcerating potentiality of acid pepsin, the other maintained in the defenses which the tissues possess and by which they protect themselves against the eroding action of gastric chyme.

Physiologists have amply demonstrated the increased vulnerability of tissues to gastric juice of high acid pepsin value. It has often been noted that, following the use of histamine, patients with peptic ulcer continued to secrete a highly concentrated acid *for considerable periods after a retardation of secretory rates would ordinarily have been expected.* If such cellular behavior actually obtains in response to other stimuli, it would be obvious that the gastroduodenal defense mechanisms of patients with peptic ulcer might be forced to exert themselves accordingly. It seems logical that the activity of the defense mechanisms would have to fluctuate in proportion to changes in the potency of the acid-pepsin mechanisms of aggression; with prolonged and sustained elevation of acid pepsin secretion there would develop the requirements for a correspondingly vigorous effort on the part of the cells to throw out defenses against such accentuated tendencies to erosion. Ordinarily, Nature has provided that there be alternate periods of rapidity and retardation of the gastric secretory rate, thus giving the gastroduodenal cells "breathing spells" during which the forces of defense could be adequately reëstablished. Though the duodenum has remarkable reserve function in neutralizing and buffering acids, which is naturally in excess of its ordinary physiologic requirements, it will break down, however, as shown by the work of many physiologists, under the continued necessity of neutralizing the acid chyme.

Hence, the height of acid concentration and of peptic activity may be overshadowed in importance by the tendency of the chief and parietal cells to *maintain* vigorous secretory rates for unusually long periods of time. Since this maintenance of attenuated and prolonged secretory rates may represent a specific "ulcer-producing" tendency in certain patients, effort should be made to measure the potency and persistency of this factor. We at this Clinic therefore began to analyze the acid fractions as well as the peptic activity following the use of histamine for longer periods than previously. Thus we were able to measure not only the height of acidity, but also the length of time following the use of the stimulating substance through which the chief and parietal cells maintained increased secretory rates.

It then occurred to us that since it was important to know not only the maximum secretory potential of the cell, but also to have information regarding the tendency of these cells to continue to secrete with increased vigor, more might be learned by applying a second stimulation by means of histamine to the gastric glands after the estimation of the fractions gave evidence that secretory rates had approximated those present before the histamine was given. In some instances the persistence of increased secretory rates was so protracted that the second injection of histamine was made before there was much drop in acidity. Thus it was possible to observe the secretory response of the chief and parietal cells over a period of two, or sometimes three, hours. In this way it was believed that more accurate measurement of the behavior of these cells might become available.

The object of this paper is mainly to call attention to the possible usefulness of this test in adding to knowledge of gastric secretory rates. In a subsequent paper it is our intention to analyze more fully the results obtained in cases of peptic ulcer. Included in this paper, however, will be certain observations regarding acid responses in general, as well as some observations regarding the activity of peptic secretions, as noted following the use of the double histamine test.

In performing double histamine tests a small-bore Sawyer tube was introduced into the stomach and the contents were aspirated as completely as possible, after which the contents were evacuated at ten-minute periods, and in certain instances fifteen-minute periods,

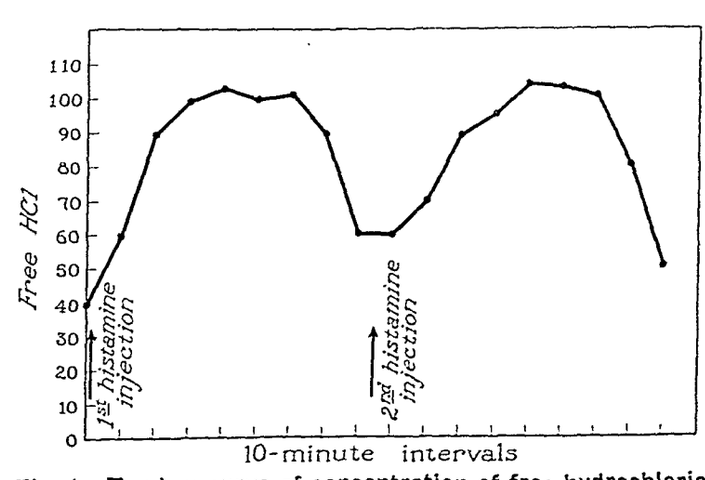

Fig. 1. Tandem curve of concentration of free hydrochloric acid produced by two injections of histamine.

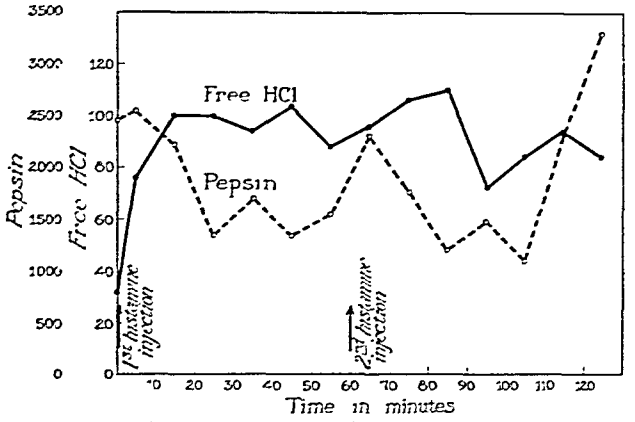

Fig. 2. Continuous black line indicates concentration of free hydrochloric acid; broken line, peptic activity following two injections of histamine.

during which unstimulated fasting secretion was removed. Histamine was then injected subcutaneously in doses of 0.1 mg. for each 10 kg. of body weight. Following this, gastric juice was aspirated for six periods of ten or fifteen minutes each. Then the same amount of histamine was again injected subcutaneously, and specimens were collected for six more periods of ten or fifteen minutes each. The volume of each specimen was measured and the concentration of acid of each was determined by titration with tenth normal sodium hydroxide, using Töpfer's reagent to determine free acid and phenolphthalein for total acid. Concentration of pepsin was estimated by the modification of the Gilman-Cowgill method described by Osterberg. Figures representing quantities of acid and pepsin secreted for each period of ten or fifteen minutes were obtained by multiplying the concentration of the substances in each specimen by the volume of the specimen.

Figure 1 shows a double or tandem curve indicating the concentration of free hydrochloric acid following two injections of histamine. The curves are fairly representative of the usual effect on gastric acid secretory mechanisms when a second injection of histamine is given sixty to ninety minutes after the first. This second response of the parietal, and incidently of the chief cells as well, is usually similar to the first.

Occasionally, in some cases there is a marked difference in the two curves, and in such instances the test may be of no particular value. Usually, however, not only is the maximal concentration of acid similar, but the persistence of cell activity indicated by the width of the curve is the same. If it has been established that in the original double histamine test both curves were similar, subsequent examinations performed within a period of two or three weeks usually again exhibit similar characteristics in both curves. Hence the second or trailer curve of subsequently performed tests can be plotted as an "expectancy" curve. Frequently, it is important to know the effect of certain ingested or injected material on the gastric secretory function. Such substances can then be given before the second injection of histamine is made. If the resultant second curve now shows gross deviation from the expectancy curve, evidence is available to suggest that the tested material was responsible for such changes in gastric chemism.

The response of the peptic cells is usually very similar to that observed in the behavior of acid cells following the use of histamine. There are many instances in which peptic activity during the course of the second histamine test was higher than it was during the course of the first test. This suggests that pepsin is not washed out from the gastric glands, but rather that it is a direct result of the stimulatory effect of histamine on the chief cells. It can be noted from a study of the pepsin curve in Figure 2 that peptic activity reached its maximum one hundred twenty minutes after the first histamine injection. It is also evident from a review of this figure that there was no retardation of acid secretory rates sixty minutes after the first injection of histamine. In such instances readings should be made at fifteen rather than at ten minute intervals and the second histamine injection should be made ninety minutes after the first. This type of curve is frequently seen in patients having a tendency toward the formation of peptic ulcer.

The secretory response of gastric cells following the use of histamine as an excitant exhibits marked inconstancy under varying circumstances. Though the behavior of the chief and parietal cells following the use of histamine may be measurable with accuracy, this probably represents only the potential response of these cells at the particular time when the test is made.

In Figure 3 are represented the curves of acidity following the use of histamine under varying conditions. In this case the vigorous secretory rate (curve A) occurs during periods in which the symptoms of ulcer are present. During periods of quiescence the rate of secretion was markedly retarded, and its response was that usually seen in normal individuals (curve B). It must not be assumed, therefore, that a single test represents a constant from which there will be no deviation in subsequent examinations. To draw conclusions based on the changes evident in curves of acidity following single histamine tests, when these tests are made at different times, may result in fallacious deductions.

CONCLUSIONS

First, it is suggested that the double histamine test might be useful in obtaining information, not only regarding the maximal potentiality of acid and pepsin secretion of gastric cells, but also regarding the

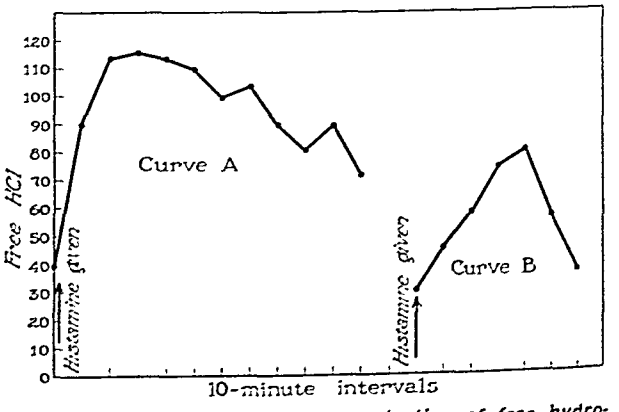

Fig. 3. Curve A represents concentration of free hydrochloric acid following administration of histamine during period of activity of ulcer. Curve B represents concentration of free hydrochloric acid following administration of histamine in period of quiescence of ulcer. Both curves represent data from same patient.

maintenance of increased secretory rates over longer periods of time. Unquestionably, this information is important. Second, by means of this test it seems possible to test with greater accuracy the effect of test substances on gastric chemistry. Third, a review of the results obtained in the double histamine test suggested the probability that the subcutaneous injection of histamine results not only in a washing out of the peptic glands, but actually in a stimulation of the chief cells to increased activity.

Phytobezoar with Visualization by Means of Gastroscopy

By

HERMAN J. MOERSCH, M.D.

and

WALTMAN WALTERS, M.D.†

ROCHESTER, MINNESOTA

BEZOARS have always caused considerable interest. In ancient times they were highly prized as charms, and valued as curative agents for various diseases. Matas, in 1914, presented an excellent antiquarian review of the disease and its history. With increase in knowledge the interest shifted to a study of the method of formation, antemortem diagnosis, and proper treatment. In spite of the excellent articles that have appeared on the subject, the number of reported cases has remained relatively limited. The case we wish to report is that of a phytobezoar, and is of special interest not only on account of the surgical treatment, but also because it is the first time that such a tumor has been visualized and recognized preoperatively by direct visual means.

Bezoars may be divided into many types, dependent on their composition. The great majority fall into one of four groups: trichobezoars or hair balls: phytobezoars, or food balls; trichophytobezoars, which are a combination of the first two; and concretions. The relative infrequency of the tumors is indicated by the report of Maes, in 1928. He was able to collect only 139 cases of bezoar from the literature, and phytobezoar had been present in only twenty-three of these cases. Smith, in 1933, brought the number up to fifty, exclusive of an indeterminate number of Harparaballi bezoars reported from India. Undoubtedly, many more, which have not been reported, have been encountered in practice, while others, which have terminated fatally, remained unrecognized, or were thought to be malignant, as in a case reported by Adams.

The etiology of phytobezoars has not been adequately determined. Balfour and Good expressed the opinion that the etiology is not dependent on any one factor. There is reason to believe, however, that they are formed at one time, as layers of accretion are not found on section. Hart and others have called attention to the high percentage of cases in which persimmons act as the primary base of phytobezoars, and said that this fruit contains a high percentage of gum and pectin, which may act as a cohesive element. This factor does not, however, hold good for other types of food, such as prunes, salsify, celery, pumpkin, and other substances, which may give rise to the formation of phytobezoars. One of the most striking features of the history of the disease is that the patient invariably has overindulged in the substance which comprises the tumor.

Fig. 1. Roentgenographic appearance of tumor of the stomach.

The symptoms of phytobezoars, especially in cases in which persimmons have been the cause of the condition, have been admirably described by Hart, and by

†Division of Medicine.

Submitted January 2, 1936.

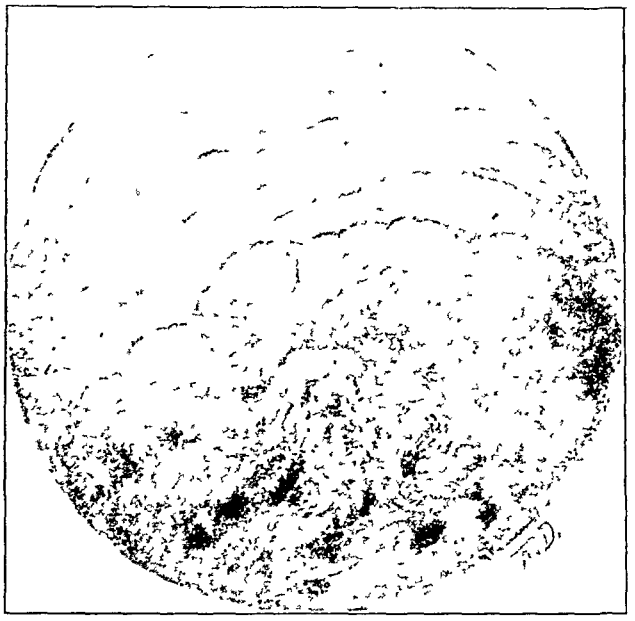

Fig. 2. Gastroscopic appearance of phytobezoar.

Balfour and Good. The symptoms consist primarily of acute gastro-intestinal symptoms, which appear within a few hours or days after the overindulgence in the fruit, if an attack is to occur. Nausea, vomiting, pain and diarrhea are present in varying degree. Smith has emphasized the frequency of hematemesis. After the first acute symptoms have subsided, the findings become bizarre, and are dependent on the size of the tumor. On physical examination, while the patient is properly relaxed, one can frequently palpate a tumor in the epigastrium; the tumor generally is movable, and may be readily mistaken for a malignant tumor. Unless the tumor fills practically the entire stomach and interferes with the ingestion of food, the patient's general health will appear surprisingly good, in the presence of such a large palpable gastric mass. This should focus attention on the correct diagnosis.

The diagnosis of phytobezoar, however, rests primarily on the roentgenoscopic findings. These have already been so excellently described by Camp, Kerr and Rypins, and by others, that they will not be mentioned here.

The treatment is primarily surgical, and this should be the procedure of choice. While relief has been obtained by manipulation and by the administration of dilute hydrochloric acid, these procedures would seem inadvisable. Potter, Butterworth, and others have called attention to the frequent association of gastric ulcer with the tumor. Judd and Phillips and Balfour and Good feel that such complications as ulcers and gastritis are attributable to trauma which is associated with the presence of the foreign body, and that the gastric lesions will rapidly subside after the foreign body has been removed. Such complications in themselves would seem to exclude any violent manipulative procedure.

REPORT OF CASE

A man, aged forty-nine years, came to the Mayo Clinic in August, 1935, complaining of "stomach trouble." He had always enjoyed the best of health until October, 1934. At this time he had gone on a persimmon "spree"; the same night he had been awakened with severe cramping pains in the epigastrium; there had been associated nausea, but no vomiting. The pain had extended across the upper part of the abdomen but had not extended through to the back. The attack had lasted about fifteen minutes, and had passed away spontaneously. Following the attack, he had had somewhat similar daily episodes of epigastric distress which had appeared about 11 a. m and 3 p. m. He always had obtained relief by taking food or milk, but not by taking alkalis. He had followed various forms of therapy without success. In January, 1935, the condition had been recognized as a phytobezoar by roentgenoscopic examination. The patient had been operated on, but, to the surprise of all concerned, no evidence of the bezoar had been found. A small healed ulcer, however, had been noted on the lesser curvature of the stomach. The patient had remained free of symptoms for six weeks following the operation, at which time the former symptoms had recurred, but had not been as severe as they had been before the operation. Roentgenoscopic examination at this time had revealed the same defect which had been noted before the operation, and a diagnosis of phytobezoar again had been made. At the time of the patient's admission to this Clinic, his symptoms were unchanged. On physical examination, a sense of fullness could be made out in the epigastrium, although no definite tumor could be felt. Roentgenoscopic examination of the stomach revealed a large multilobulated tumor in the stomach and several associated smaller masses. It was difficult to displace the large tumor from the cardiac end of the stomach The lesion was thought to be a phytobezoar (Fig. 1). The gastric analysis revealed 150 c.c. of gastric juice at the end of an hour. The value for the total acidity was 56, and that for the free hydrochloric acid was 42, according to the method of Topfer.

From the history and roentgenoscopic findings, a diagnosis of phytobezoar was made, and operation was advised. In view of the previous findings at exploration, the patient requested further corroborative evidence before submitting to operation. Gastroscopy was suggested, and requested by the patient. On gastroscopic examination, a large tumor was found to be situated in the middle and cardiac end of the stomach, on the posterior wall. It was

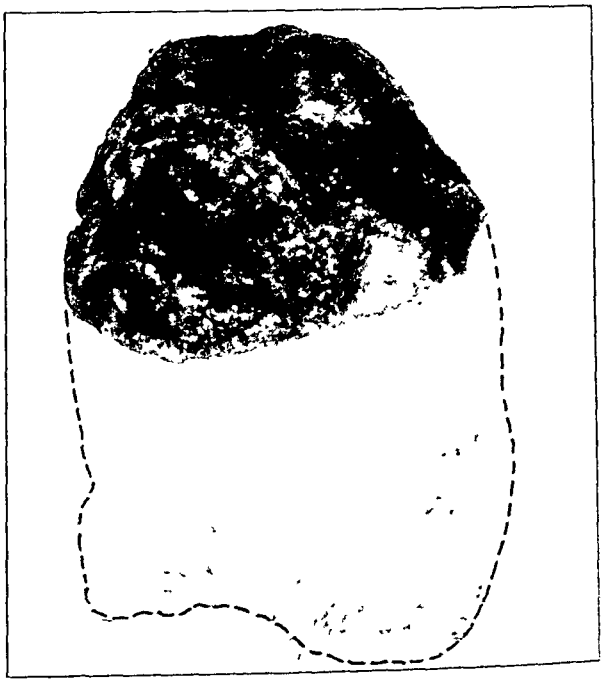

Fig. 3. Phytobezoar after removal; dotted line indicates full size of tumor; exposed portion corresponds to portion visualized with the gastroscope.

impossible to move the growth by pressure with the end of the gastroscope. Figure 2 represents the gastroscopic appearance of the tumor.

With the added information the patient not only was willing, but desired, to undergo another operation. A gastrotomy was performed by one of us (Walters), through a left rectus incision. A movable rock-like tumor mass, approximately 7.5 by 10 cm., was palpated in the lower third of the stomach. A small longitudinal incision was made through the anterior wall of the stomach. Impacted in the lower third of the stomach, just above the pyloric sphincter, was a black ovoid foreign body. It required some force to dislodge this foreign body (Fig. 3). There was a good deal of inflammation in the gastric wall adjacent to and above the foreign body. Exploration of the interior of the stomach with the hand brought out three or four gelatinous-like masses, each about 2 by 3 cm. in size. There was no evidence of an associated gastric ulcer at this time. The incision in the anterior gastric wall was closed in the usual manner. The patient made a rapid and uneventful convalescence, and has remained free of symptoms since the operation.

COMMENT

This case illustrates two salient features: First, bezoars may be movable and at times may escape from the operative field and escape detection, as has been previously described by Outten, in Hart's report. Second, in certain selected cases, gastroscopy may be of value as an added diagnostic procedure.

Functional Abdominal Distention Simulating Megacolon

By

J. ARNOLD BARGEN, M.D.*
ALFRED W. ADSON, M.D.†
JOHN S. LUNDY, M.D.‡
and
CLAUDE F. DIXON, M.D.§
ROCHESTER, MINNESOTA

FROM time to time, patients present themselves for examination with very marked abdominal distention which simulates organic intestinal obstruction or the distention of megacolon. The diagnosis of intestinal obstruction is usually readily made, but in these cases, careful objective investigation is necessary to distinguish between the distention of intestinal obstruction, true megacolon, and functional abdominal bloating.

REPORT OF CASE

A single woman, aged forty-two years, came to the Mayo Clinic March 18, 1935, complaining of abdominal pain and huge bloating of the abdomen. She had been constipated all of her life and had taken all kinds of cathartics as long as she could remember. She did not remember ever having had a normal bowel movement. However, in the last three years, she had become much worse than she had been; even 4 to 6 ounces (112 to 180 c.c.) of castor oil had not effected a bowel movement. She remembered that as a child she had had a bowel movement every three to five days; at these times, the stools had been as hard as a rock, and she had screamed with pain during the forced passage. During the last thirty years, she always had taken laxatives. In 1918, all of her family, which consisted of six sisters and one brother had had influenza. Besides teaching school, she had nursed these members of her family. During this time, she had had a spell of unconsciousness which had been followed by shaking of the hands which had been diagnosed as "chorea." In 1922, an appendectomy had been performed for recurring pain in the right lower quadrant of the abdomen. Temporary relief had followed. After this, she had had another attack of athetoid movements of the arms and legs, with peculiar facial grimaces, which had lasted for six months. In June, 1931, she had had similar trouble which had lasted for eight months. After this attack, "she had to learn to walk all over again." In October, 1932, she had begun to have what she called a "stomach ache." She first had noticed abdominal distention in December, 1932. Examinations at home had not revealed any organic disorder, and a Mediterranean cruise had been advised. She had become very ill on the boat. The illness had been associated with great distention of the abdomen and much vomiting. She had spent two months in the American Hospital in Paris, where a diagnosis of chronic disseminated encephalomyelitis with super-added psychoneurosis had been made. At that time, the abdominal disturbance had been interpreted as "paralytic ileus." She had returned to America in September, 1933. In June, 1934, she had been on the neurologic service of a large hospital in New York. The abdominal distention had persisted from its

Submitted November 26, 1935.

Fig. 1. Elongation and slight distention of the colon.

first inception in 1932. In July, 1934, her family physician had administered pituitrin, which had produced relief of the abdominal distention, explosive expulsion of gas, and then normal bowel movements. From then until her visit to this Clinic in March, 1935, she had taken pituitrin every one to three days. This had relieved the distention temporarily. She had been sent to this Clinic with the suggestion that she might have a megacolon of the Hirschsprung type.

Examination revealed that the patient was 55 inches (139.7 cm.) in height and weighed 81½ pounds (36.8 kg.). She said that other members of her family were small. The values for the systolic and diastolic blood pressure were 140 and 100 mm. of mercury respectively. This varied from time to time; the average values were 114 for the systolic, and 78 for the diastolic pressure. She appeared to be of a cheerful disposition but obviously was in considerable discomfort. The size of the abdominal distention suggested a full-term pregnancy. The abdomen was soft but somewhat tympanitic. A spinal lordosis was apparent. The digital examination of the rectum at once denied the presence of a megacolon, at least in the distal portion. Proctoscopic examination showed a normal rectal and sigmoid lining. The anal sphincters were large and appeared to be thicker than they normally should be, and two or three times as wide. The lumen of the rectum and sigmoid seemed normal in its dimensions. Roentgenologic studies of the colon showed it to be elongated slightly, and perhaps a little distended (Fig. 1). Fluoroscopic examination of the thorax and diaphragm showed normal diaphragmatic movements. Roentgenograms of the head and of the small intestine did not reveal anything unusual. Repeated urinalyses disclosed that the urine was essentially normal. Examination of the blood did not disclose any abnormality. The value for the urea was 18 mg., and that for the sugar was 94 mg. per 100 c.c. of blood. The values for the sulphates and calcium were 3.5 and 10.1 mg. respectively, per 100 c.c. of serum. The sedimentation rate of the erythrocytes did not reveal any unusual changes.

Further intensive study of the nature of the abdominal distention was undertaken. A bilateral splanchnic block was induced. The patient was placed on the operating table; at this time, the abdomen was moderately distended (Fig. 2a). No peristalsis was audible. There was a marked lordosis of the back (Fig. 2b) and a large hand easily could be slipped between the arched lumbar region and the table. Before five minutes had elapsed following the injection of the procaine in the splanchnic region, the abdominal distention began to disappear. During the most marked flattening of the abdomen, the lumbar region of the back was flat on the table. When the distention began to disappear, peristalsis was audible. This seemed to be of a normal type. There was no passage of flatus or belching of gas during the disappearance of the distention. Among the symptoms noted during the period of splanchnic block were complete aphonia and inability of the patient to sit up on the table. She insisted that she could not see. During this time, the blood pressure, pulse, and the color of the skin were normal. Within fifteen minutes after the injection, the abdominal distention began to recur. Twenty-five cubic centimeters of 1 per cent solution of procaine-novocaine, with epinephrine had been injected. It was one and a half hours before the abdominal distention returned to about its original condition. Sterile normal saline solution, which was injected a few days later in a similar way, produced relief which was less marked than that which occurred after the bilateral splanchnic block. Three days later, the patient again was taken into the operating room. Her knees were flexed and brought toward the head. This caused complete relief of the abdominal distention. At none of these times was gas passed from any of the orifices. Many drugs were administered

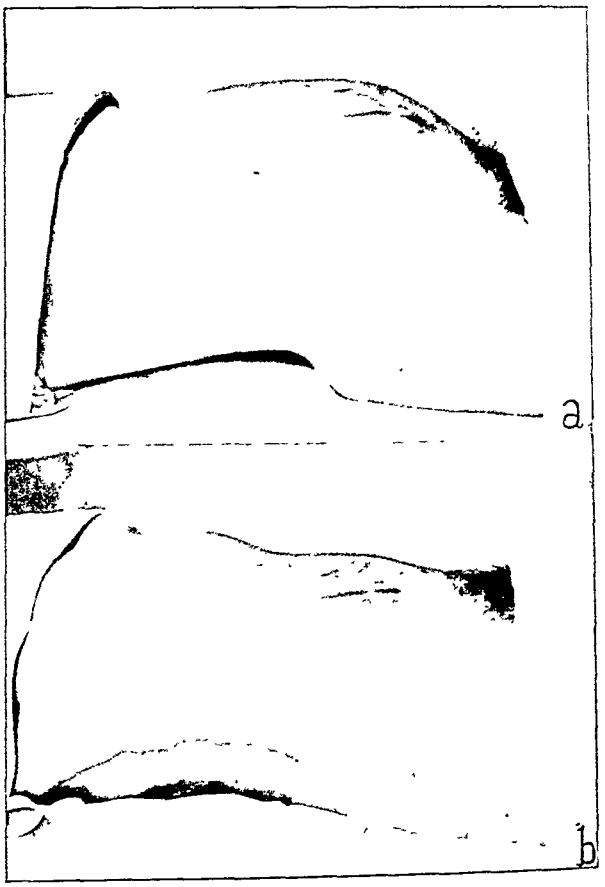

Fig. 2. Condition of abdomen; A, before, and B, after induction of splanchnic anesthesia; injection of physiologic saline solution, injection of sodium ethyl 1-methyl butyl thiobarbituric acid (thionembutal), and other manipulations which distracted the patient's attention.

in an effort to relieve the abdominal distention. Sufficient epinephrine to produce physiologic effect was administered hypodermically, with the thought that this phenomenon might be of the nature of an angioneurotic edema. Physostigmine salicylate was administered in doses which were large enough to produce systemic effects. Tincture of belladonna and sedatives also were administered. None of these drugs gave relief from the abdominal distention. Complete and prompt relief resulted from the injection of surgical pituitrin, and sodium ethyl l-methyl butyl thiobarbituric acid (thionembutal) which was administered intravenously to produce anesthesia, gave prompt relief without the passage of gas. A careful examination of the central nervous system did not reveal any objective organic disease. These tests led us to conclude that the abdominal distention probably had a functional basis. Surgical interference did not seem wise. An anticonstipation regimen and mild sedatives were advised, and she was dismissed on April 22, 1935.

This patient returned to her home. Improvement was only slight and progress did not seem satisfactory. A letter from her family physician, dated September 24, 1935, revealed that a bilateral sympathectomy had been performed and that definite immediate improvement had followed this operation. The letter was dated three weeks after the operation.

COMMENT

Our past experience with cases of this type would lead us to suggest that such a patient should be observed for several years before arriving at a conclusion about the efficacy of any therapeutic endeavor.

Patients with functional abdominal distention present grave problems. There is something about them which smacks of willful invalidism, as in other factitial disorders, and yet if such is the case there seems to come a time when the condition passes beyond the control of the individual. The danger in these cases is the confusion with real organic intestinal obstruction, and hence, of unwarranted surgical interference. A psychologic approach to the problem and a conviction of the functional nature of the condition seems so far to be the keynote to the best treatment.

Pyogenic Skin Lesions Accompanying Chronic Ulcerative Colitis;*

Report of Five Cases

By

I. R. JANKELSON, M.D.

and

B. F. MASSELL, M.D.

BOSTON, MASSACHUSETTS

RECENTLY we have seen five patients who, in the course of ulcerative colitis, developed ulcerations of the skin. This complication, though uncommon, is not only interesting but also important, in that it is often difficult to control. In fact, in one of these cases it was directly responsible for death.

Although a great deal has been written about ulcerative colitis and its more common complications, very little mention has been made concerning skin ulcerations. A rather extensive search revealed but nine such reports. Bargen (1, 2) discussed the condition among other complications. Rankin, Bargen and Buie (3) in their book included a picture of a leg with such lesions.

Warner (4) reported a case of ulcerative colitis in a child, seven years old, with recurring crops of blebs on the skin and mucous membrane of the nose, throat and mouth. The blebs resembled those of pemphigus.

Brunsting, Goeckerman and O'Leary (5) described lesions occurring in patients with long-standing infection elsewhere in the body. Of five cases which they reported, four had ulcerative colitis and one chronic empyema. The skin lesions were small discreet pustules surrounded by an inflammatory areola. These softened, ulcerated and extended peripherally in a rough serpiginous configuration. The borders were boggy and blue in color. There was extensive undermining and necrosis of the subcutaneous tissue.

In 1933 there appeared a report from the Massachusetts General Hospital (6) of a case of ulcerative colitis with numerous complications including pustular skin lesions. At about the same time Jones (7) described two patients with skin lesions and ulcerative colitis. One, a twenty-six year old male had several areas situated on one arm about an inch in diameter which were red, indurated and tender. There were also smaller nodular lesions elsewhere. Another patient, a 37 year old male, had a pustular skin rash, red papules and small pustules on the pharynx and finally developed an ulceration of the cornea.

Brooke (8), described lesions suggesting an erythema nodosum in a 23 year old female with ulcerative colitis. On various parts of the body, but most marked on the anterior aspect of the legs there were raised tender purplish-blue areas which enlarged and became soft and fluctuant. One of the lesions on the anterior tibia broke down and sloughed, leaving a large ulcerating area over most of the lower leg.

A recent paper by Mackie and Henriques (9) included a brief report of an intensive spreading of skin gangrene of the flank in a patient with ulcerative colitis. Multiple secondary foci surrounded by normal skin appeared.

The following are the five cases to be reported in this paper:

Case No. 1, S. V., a twenty-three year old college student was admitted to the hospital on Feb. 24, 1934, with the chief complaint of severe diarrhea.

*From the Medical Service of the Beth Israel Hospital.
Submitted October 6, 1935.

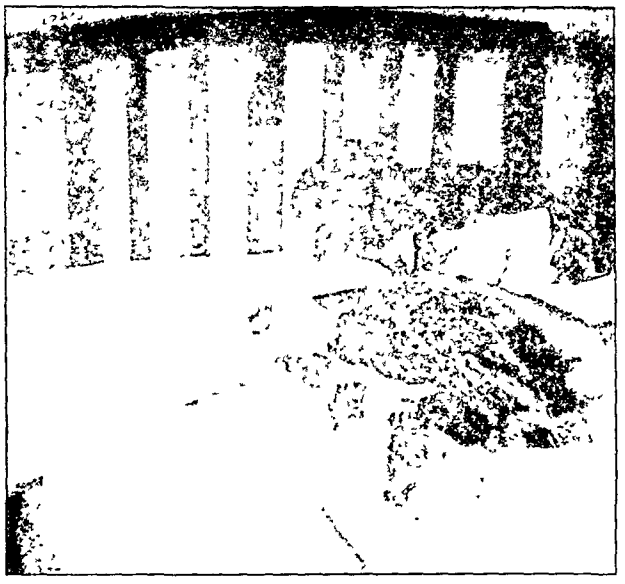

Fig. 1. Picture of the back of Case No. 1. Note the deep and extensive ulcerations of the skin and underlying fascia.

His family history and past history were essentially negative.

About two and one-half years before this admission, he began to have bloody diarrhea which continued intermittently for a period of about six months. A diagnosis of ulcerative colitis was made on the basis of a Roentgen-ray examination and sigmoidoscopy.

About three weeks before admission to the hospital, after a period of almost eight months with fairly normal bowel movements, there was a sudden onset of severe watery and bloody diarrhea, with as many as 15 to 30 bowel movements daily. After being in bed for about two weeks he developed boils which rapidly spread over his back and became particularly severe and painful during his last two days at home.

Physical examination. On admission revealed a fairly well-developed and well nourished young man, apparently very uncomfortable. Over his entire back and to a lesser extent on the upper lateral aspects of his thighs there were numerous furuncles ranging in size from two to four cm. in diameter. Several of these were discharging yellow pus. Examination was otherwise essentially negative.

Clinical pathology. Urine was essentially negative. Stools were liquid and contained occult blood. He showed a moderate secondary anemia. Culture of pus from furuncles showed staphyloccus aureus. Blood culture was negative.

Clinical course. The patient was in the hospital for eighteen days. He continued to run a septic temperature reaching as high as 103 to 104 (by rectum) daily. The diarrhea continued, uninfluenced by diet or medication. Within a few days the furuncles had opened and discharged yellow pus, leaving large ulcerated areas whose borders rapidly spread peripherally so that at the end of a week most of them had become confluent, thus forming very large granulating areas with edges of dirty gray necrotic tissue (Fig. 1). During the last week he was drowsy and at times delirious. Finally, eighteen days after admission there was a sudden rise of temperature to 107, pulse to 180, and respiration to 35, and within six hours he was dead.

Autopsy performed by Dr. M. J. Schlesinger showed the following significant findings: Over the back extending from the level of the seventh cervical vertebra to the iliosacral region and from the posterior axillary line on the left to the posterior axillary line on the right there was an extensive ulcerating granular process with raised irregular and undermined skin edges. Here and there in the center of the process could be seen purplish discolored islands of skin. No pus could be seen either in the form of gross exudate, or in the form of pustules. In the center of the process the ulcerations had extended to the fascia of the muscles, while towards the periphery only the superficial portion of the skin had been affected, the process limiting itself to the corium. At the edges of the lesions were small nodules of purplish necrotic skin.

Similar ulcerating areas measuring 10 to 15 cm. in diameter could be seen over the upper portions of both scapulae and on the lateral aspect of the right thigh separated from the large lesion by an area of intact skin.

Microscopic examination revealed no evidence as to the etiology.

The colon showed the typical chronic ulcerative colitis lesions. No amoebae were found.

Case No. 2, A. S., a 27 year old married business man with an irrelevant family history and a negative past history except for scarlet fever at the age of nine, came to the Beth Israel Hospital on March 4, 1934, with a chief complaint of diarrhea of 2½ months duration. About a month after the onset, he developed on his right leg without apparent cause, a slightly painful sore which failed to heal. For two weeks previous to admission he had fever reaching as high as 102 and a persistent sore throat. The latter caused such difficulty in swallowing that he was unable to take nourishment.

Physical examination revealed a well developed but poorly nourished young man rather pale and moderately sick in appearance. In the right tonsillar region there was a large ulcerated area covered with a greyish membrane. On the calf of the right leg there was a dime sized punched out ulcer, with a slightly raised red margin, extending entirely through the skin into the subcutaneous

Fig. 2. Illustration of a leg of a patient with chronic ulcerative colitis. Reproduced by courtesy of authors from Rankin, Bargen and Buie "Colon, Rectum and Anus." W. B. Saunders Co., Philadelphia.

tissue. The examination was otherwise essentially negative. His blood pressure was 110/80.

Clinical pathology. Urines showed a specific gravity of 1.010 to 1.014 with 0 to slight trace of albumen, 5 to 30 pus cells and 5 to 30 RBC. Blood showed a moderate anemia. Stools were liquid and grossly bloody. No amoebae were found. Blood NPN. was 65. Culture of throat and leg ulcers showed staphylococcus aureus and haemolytic streptococcus. Urine cultures—on two occasions showed staphylococcus albus; on one occasion—no growth. Blood cultures were negative. Culture from ulcer of colon (taken at sigmoidoscopy) showed B. coli, staphylococci, and streptococci.

A diagnosis of ulcerative colitis was confirmed by sigmoidoscopy and barium anema.

Clinical course. Throughout his stay in the hospital the patient had a low grade fever. Two days after admission another ulcer appeared on the buccal surface of the mouth. Because of his painful throat it was difficult to get him to take fluids by mouth. The blood NPN. had risen to 115 and the patient was slightly drowsy. He was given large amounts of fluids under the skin and by intranasal catheter for three days. As a result there was an increase in the urinary output and the throat and mouth lesions became less painful so that he was able to take sufficient fluids by mouth and later a low residue diet. His bowel movements became less frequent, gradually became pasty and contained less blood. The blood NPN. fell; his throat and mouth lesions healed still further, and he felt generally better.

At the time of discharge from the hospital, 23 days after admission, the ulcer on the leg had granulated in very well and was beginning to epithelialize. The mouth and throat ulcerations had entirely disappeared.

Bowel movements were semi-formed, reduced to two daily and no longer contained gross blood although they were still guaiac positive. The blood NPN. had dropped to 29 but the urine still showed albumen, white cells, red cells, and casts. His general condition was markedly improved.

Case No. 3, J. C., a 28 year old printer, in the short period of two and one-half years was admitted to the Beth Israel Hospital five times because of ulcerative colitis and associated complications. His illness began suddenly, early in 1932, with severe bloody diarrhea and abdominal cramps, followed shortly by marked weakness and loss of weight. Because of peri-anal abscesses and persistent activity of his ulcerative colitis, an ileostomy was performed. In February, 1933, he developed superficial furuncles all over his body.

In June, 1933, an abscess formed over the lateral aspect of the left ankle. This was incised and drained at home. It continued to become progressively more painful and swollen so that on July 22, 1933, he was again admitted to the hospital. Local examination showed over the left lateral malleolus and lateral aspect of the left foot a large red hemispherical swelling which was soft, fluctuant and tender. There were numerous small openings which discharged a yellow pus. This carbuncle was incised and warm boric compresses applied. On July 30 the entire surface sloughed away leaving a granulating area 12 cm. in diameter. With saline dressings the granulating area became clean and on August 17, pin point grafts were applied and "took." He was discharged on August 22, 1933.

Six weeks later the swelling of the left ankle recurred and was drained.

Clinical pathology was essentially negative expect for hypochromic anemia.

On November 2, 1934, he was admitted to the Bickur Cholim Hospital for chronic care. While at that institution he developed further abscesses on his feet, associated with an exacerbation of bloody diarrhea and arthritis.

A culture taken from a freshly opened large abscess of his left ankle showed a pure culture of staphylococcus albus. A similar culture takn through a sigmoidoscope from the base of an ulcer in the sigmoid showed the same organism. Therefore, an autogenonous vaccine was prepared and inoculations given. This was followed by striking results in clearing both his skin lesions and his ulcerative colitis symptoms.

Case No. 4, R. L., an eighteen year old girl was admitted to the Medical Service on March 11, 1932, with the chief complaint of intermittent bloody diarrhea and abdominal cramps of one year's duration.

Physical examination was essentially negative except for marked undernourishment and tenderness over the lower abdomen.

A diagnosis of chronic ulcerative colitis was made on the basis of sigmoidoscopic and Roentgenologic evidence.

She remained in the hospital for 5 days and then left against advice.

On June 2, 1932, she was again admitted to the hospital, this time to the surgical service, because in spite of medical treatment the diarrhea and cachexia had become progressively worse. Over the anterior aspect of both feet there were superficial ulcerations—the right about 2x3 cm., the left 4x5 cm. in area. Both were covered by pink granulations.

Her general condition remained poor, in spite of two transfusions. On June 4, 1932, an ileostomy was performed and pin point grafts were applied to the skin ulcerations.

The cutaneous lesions healed, but bloody discharges from the rectum continued. In spite of the well functioning ileostomy her general condition remained extremely poor. Throughout her stay she was uncooperative and unmanageable so that treatment was difficult. On July 26, 1932, she left the hospital once more against advice.

She continued to pass blood and mucus by rectum. On June 5, 1934, 1½ years later, she was seen on the emergency ward where examination showed the same severe emaciation, and a well functioning ileostomy. At that time she again showed some pustular involvement of her ankles.

Case No. 5, L. B., a 43 year old married woman, with an irrelevant family history and past history, was first admitted to the Beth Israel Hospital on December 18, 1933, because of bloody diarrhea of four weeks' duration. She always had had four well formed bowel movements daily. She had fever and lost weight.

Physical examination on admission was essentially negative except for slight pallor.

Sigmoidoscopy showed a marked redness and swelling of the mucous membranes of the rectum and sigmoid. No ulcerations were seen at that time but later examinations showed pin point ulcerations. A culture from one of these ulcers showed staphylococcus albus and B. proteus.

After a 19 day stay in the hospital on a medical and dietetic regime, she had improved sufficiently to be discharged home.

There she did fairly well until September, 1934, when there was an exacerbation of the bloody diarrhea. After this had continued for two weeks, two indurated red areas, about 4 to 5 cm. in diameter, appeared on the right thigh and left buttock, and she had pain on the spine. Ten days later an abscess formed on the dorsum of the right little finger.

She was admitted to the Beth Israel Hospital for the second time on October 8, 1934, and the abscess was incised and drained. Under medical regime the colitis improved. However, the local infection of the little finger persisted and X-ray revealed an osteomyelitis. The cultures of the pus from the abscess showed staphylococcus albus.

DISCUSSION

These five cases have much in common. All occurred in chronic idiopathic ulcerative colitis during the height of an acute exacerbation. All had febrile reaction, were more or less toxic and had an active diar-

rhea with watery stools, containing mucus, blood and pus. The two patients who had an ileostomy showed considerable muco-purulent-sanguinous rectal discharges. In none of these cases could either Bargen's organism or entameba histolytica be isolated. Bacillary dysentery was excluded by negative cultures and specific agglutination tests. Various organisms were cultured in three cases from smears taken from the base of the ulcers in the sigmoid. The organisms cultured were staphylococcus aureus, staphylococcus albus and the hemolytic streptococcus either separately or together, but there is no evidence as to whether these were the primary cause of the lesions or secondary invaders. In two out of three cases the same organisms were found in the skin lesions as in the ulcers of the intestinal mucosa. This suggests the possibility of a metastatic origin of the skin infection. However, we have no proof that metastatic infection has actually occurred in these cases or in any of the cases reported in the literature.

A lowered resistance to infection seems to play an important role in the etiology of these skin ulcerations, whether these are caused by organisms which get into the skin by direct invasion or are carried there through the blood stream from the diseased colon. In those instances in which recovery took place, improvement in the skin ulcerations accompanied improvement of the general condition of the patient.

The skin lesions encountered in these five cases as well as those described in the literature vary a great deal in severity. In some cases they were merely punched out ulcerations or redness, swelling and induration without abscess formation, in other cases there were multiple distinct abscesses. In Case One, as well as in the case illustrated in Rankin, Bargen and Buie's book (Fig. 2) there were deep ulcerations involving a large part of the skin and subcutaneous tissues. It is interesting to point out, that an ileostomy does not prevent any distant skin involvement, provided that the colon infection persists, as it frequently does. The skin infection occurred in Case Three 15 months after an ileostomy and in Case Four—18 months. In both cases infection of the colon persisted in spite of the operation and a colectomy was advised but rejected by the patients. The amount of colon involvement does not seem to bear any relationship to the severity of the skin infection.

The early skin lesions often resemble toxic skin diseases. In the literature we found some references to these manifestations as pemphigus, blebs and erythema nodosum. Their course, however, is not typical and in most cases pyogenic infection occurs.

The treatment of the pyogenic skin infections in the course of an ulcerative colitis is largely symptomatic. Incision and drainage of single abscesses, heat —dry or moist—in the punched-out ulcerations. In the one case in which autogenous vaccine was tried, the results were apparently excellent. When the infection is widespread and deep the management may become very difficult and the prognosis serious. In one case the skin infection was the primary cause of death. The treatment must naturally be directed at the same time to the management of the primary disease, namely the chronic ulcerative colitis. Whatever management will cause a remission of the chronic ulcerative colitis will contribute to the healing of the pyogenic skin infection.

SUMMARY

Five cases of chronic idiopathic ulcerative colitis complicated by infection of the skin are presented. In all cases the skin infections occurred during the height of an exacerbation and in four of the five cases subsided together with the remission of the colitis. One case succumbed to the infection.

The possible mechanisms which play a part in the skin infections during the course of an idiopathic ulcerative colitis, are discussed. The skin lesions as encountered in this series as well as those in the literature are described. The treatment is outlined.

Is Phenolphthalein Harmful?

By

PROF. ZOLTAN v. VAMOSSY*
BUDA PEST, HUNGARY

IT becomes necessary to discuss this question for the following two reasons: first, because I was the one to introduce phenolphthalein as a laxative; and, secondly, because of the occasional unfavorable reports regarding its use.

Before proceeding any further, I wish to correct the erroneous impression as to the manner in which I came upon the action of this drug. It is stated that phenolphthalein was advocated for the denaturing of wines made from the husks of grapes (artificial wines used by the poorer classes who added sugar water to the pressed husks of grapes and allowed it to ferment), and that diarrhea was then observed following the use of such wines. It is unfair to the Hungarian Govern-

*Director, Pharmacological Institute of the Royal Hungarian University at Buda Pest.
Submitted November 2, 1935.

ment to think that they would have permitted anything to be added to any drink without previously investigating its effect on the health of its people. The Federal Public Health Council has functioned in Hungary since 1876. Every Federal regulation and licensure regarding the use of drugs has to pass through this body, and even to this day the sale of phenolphthalein in the form of chewing gum or candy is restricted to chemists and cosmetic shops, and it cannot be obtained elsewhere. It must be sold in packages accurately labeled as to the active ingredient and the dose. That the laxative properties of this drug could not possibly have been discovered by the drinking of adulterated wines, may be noted from the following. Phenolphthalein turns pink in an alkaline solution even in a dilution of one to ten millions; and, as the amount of phenolphthalein that is needed to detect these wines is infinitesimal (0.1 Gm. to 100 liters), it would be necessary, even if 1 Gm. were used, to drink at least 10 liters of the wine before diarrhea would develop.

When it was proposed to denature artificial wines with phenolphthalein, I was first entrusted with the task of investigating the harmlessness of this reagent. I carried on numerous experiments on animals with negative results. One small pet dog that received 6 gm. of phenolphthalein became quite constipated and passed fecal masses as if it had been fed on a diet of bones, but these fecal masses became crimson on the addition of alkali. Following this, the drug was tried on man. A colleague took 1 gm. and I took 1.5 gm. of phenolphthalein at 11 a. m. The effect appeared between 1 to 3 p. m. that afternoon, in the form of three to five watery evacuations accompanied by some borborygmi. A similar action occurred that evening and also the next morning, but in no way disturbed us from our regular afternoon laboratory work or our night's rest. I became convinced that I had discovered a laxative of great merit. It was easy to take owing to its tastelessness. It did not gripe and did not seem to have any drastic effect even in large doses (1.5 gm.). It was later found that 0.1 gm. taken in the evening emptied the contents of the colon the following morning, resulting in a copious but soft movement. Our clinical co-workers had the same experience with this drug and obtained the same results, emphasizing that they found no contraindications to its use in various organic disturbances, not even in patients suffering from kidney affections. Of particular value was the report of pediatricians that children and even infants reacted well to this laxative and showed great tolerance to it. The pediatricians preferred it to the troublesome castor oil because phenolphthalein was mild in action and pleasant to take. Other clinicians noted that bedridden patients required a greater dose of phenolphthalein than ambulant patients. Febrile patients were more resistant to the action of this drug, owing to the recognized physiological and pathological behavior of the intestinal tract in such states.

I therefore introduced this laxative in 1902 (1) on the basis of animal experiments, on observations on myself and my associates and also on its clinical trial in a great many adults and children. I made the statement then, and I still believe so today, that phenolphthalein is harmless. It has received support from many clinicians who cited their experience in thousands of cases where this laxative was used without any mishap (2). You read in some of the literature that phenolphthalein may cause irritation of the kidneys, yet these observers never noted such ill effects pertaining to the kidneys or any of the other excretory organs. It is a laxative in common use for many years, particularly in the United States, where the sales last year, according to the U. S. Tariff Commission, amounted to 451,418 pounds. This means that several billion doses of phenolphthalein in various preparations, were consumed in 1933 alone. The numerous reports of overdoses with no ill effects (3) also supports my contention of the harmlessness of the drug. Among these will be found an instance where a child, 3½ years old, took as high as 96 grains of phenolphthalein with apparently nothing more than the added purgative action and some slight vomiting (see footnote 3f).

There are about twenty separate instances cited in the literature where some general disturbance has been attributed to the use of phenolphthalein. I consider most of these reports as not definitely proven. Sollman (4) states that the reactions reported by Holz (5a), Best (5b), Zabel (5c) and others, are doubtful in nature. Hydrick (6) detected a transient albuminuria following an average dose of phenolphthalein. Other observers (7) failed to confirm the findings of Hydrick. Assuming that the reported reactions are due to phenolphthalein, it still shows that considering the enormous number of doses consumed, such reactions are so few as to be practically negligible, no more than can be accounted for by an unusual idiosyncrasy of certain individuals.

My endeavors to reveal the mode of action of phenolphthalein were futile, and to this day I can only speak of the probability of one theory. The reason for this is primarily due to the fact that the drug is inactive in animals except with large doses frequently repeated. I did notice purgative effects from phenolphthalein in cats living on a milk diet but these experiments were not conclusive as this occurred in a number of other cats as a result of feeding milk alone. The fact that this drug seems to be effective in man only points to interesting but unexplained differences between the bowel functions of mammals and man. The watery evacuations that follow the use of phenolphthalein in man resemble those produced by salts of low diffusing capacity. This led me to consider the possibility that in the human intestine phenolphthalein forms a sodium salt leading to fluid retention which becomes responsible for the mild laxative effect. Indeed my experiments with diffusion funnels have shown that a 1% solution of the sodium salt of phenolphthalein is capable of holding so much water that the fluid in the diffusion funnel reached the height of 3 meters while the animal membrane bulged considerably downward. After many unsuccessful experiments the 1.25% solution—as computed from the lowering of the freezing point—proved the osmotic pressure to be equal to 1.75 atmospheres.

However, the theory that the mode of action of phenolphthalein was due to the formation of a sodium salt of low diffusion properties, could not be maintained in view of the fact that small doses of the drug

were effective. Such great molecular action could not be expected from such minimal amounts. Furthermore, although the drug has been in use for many years, examinations of the small intestinal contents of man at autopsy, have never revealed them to be of a pink coloration, nor could this be observed in any of my experimental animals. This, however, can be explained because the alkalinity of the small intestine is not due to a strong alkali but to sodium bicarbonate. Its absorption amounts to very little, for 87% of the drug was recovered from the feces of a dog which had received 3 gm. of phenolphthalein.

The question has been raised, does phenolphthalein injure the liver? This originated with Dr. F. J. Cullen, formerly director of the U. S. Federal Food and Drug Administration in Washington, who accuses phenolphthalein of causing injury to the liver tissue. I have never read or heard of such an effect on the liver, and assumption is far from proof. On the contrary, several investigators have used the drug in patients with acholic stools and have found its action favorable (8). Cases have been reported where the halogen compounds of phenolphthalein used in roentgenography of the gall bladder—tetraiodophenolphthalein, phenoltetrachlorphthalein, tetrabromphenolphthalein—have caused injury to the liver. Some of these have laxative action but cannot be considered in the same light as phenolphthalein, from which they differ chemically. It is certain that the reports of injury to the liver produced by the halogen compounds, have been confused and wrongfully attributed by Dr. Cullen to phenolphthalein.

Phenolphthalein acts as a laxative but is of no value for any of the diagnostic procedures for which the halogen compounds are used. Practically ninety per cent of phenolphthalein is immediately excreted with the intestinal excretions. The drug cannot be detected three or four days after ingestion. The rare instances in which a reaction occurs may only be due to the comparatively small amount of the drug that is absorbed, which either induces sensitization or else produces symptoms in one already sensitized. There is reason to believe that the small amount of phenolphthalein absorbed is converted into a conjugate, probably a sulpho-compound. If so, it is harmless because another sulpho-derivative of phenolphthalein—phenolsulphonephthalein—is being used intravenously as a kidney function test, and so far no ill effects have been noted following its use.

Phenolphthalein has established itself as a useful laxative. Its effect is limited to the intestinal tract. It has found its way into every pharmacopoeia and various other medical texts, but in none is it listed as a poisonous drug. Its popularity is reflected by the numerous laxatives, digestive mixtures, cholagogues, etc., on the market, containing phenolphthalein. I derive great satisfaction in contemplating the benefit that physicians have achieved with this drug in patients. When one compares the few "reactions" reported with the countless instances in which the drug is used without any ill effects, such "reactions" must be considered mostly as pure coincidences. No one should take the reports of such ill effects seriously unless they are unqualifiedly proven.

The most characteristic example of a fortuitous "reaction" is that recently reported by Cleeves (9), who observed the death of a boy 10 years old, following the taking of an overdose of phenolphthalein. I will include here the clinical history and post-mortem findings of this case in full, in order to present a clear view of the entire case.

One-half box (1.15 Gm. of phenolphthalein) of the well-known American purgative, Ex-Lax tablets, was taken by a ten-year old boy. A copious diarrhea developed which passed off without trouble and without any medication. The following day the temperature rose to 41° C. and because of this Dr. Cleeves who was called, prescribed bismuth powders. The boy felt much better on the next day of his illness but owing to the continued fever, another physician was called, who prescribed sodium salicylate. The boy's pulse was 130. The fever persisted and on the fifth day a sudden eruption of huge wheals with sharply marginated serpiginous borders developed on the abdomen, legs and arms, and lasted for twenty-four hours. On the sixth day of illness, hemiplegia was noted and the child became delirious. Multiple petechiae appeared on the abdomen and subcutaneous hemorrhages developed on the feet. The fever remained at 40° C. Coma finally supervened, with gradual failure of respiration, and the child died on the ninth day after taking the laxative. His urine was examined repeatedly and remained normal until the last day when blood appeared in it.

No stool or blood studies or histological examinations of the skin lesions, nor a chemical examination was made during the boy's illness or after death. At the post-mortem, a great many hemorrhages were found in the intestine as well as in all organs such as the kidney, liver, brain, meninges and cardiac muscle. Infarcts were noted in the aortic valves. The spleen was four times the normal in size, soft, dark red, and the adrenal glands were almost liquified. In the right island of Reil of the congested brain, a large size hemorrhage was visible which was probably the cause of the hemiplegia. The pathological picture was that of a systemic vascular disease.

Any one who reviews this clinical history and post-mortem findings with careful attention to all the details in this case, would immediately see that the condition had nothing whatever to do with the drug and that one is dealing here with a severe toxic effect, the latent period of which happened to coincide with the taking of Ex-Lax tablets. How and when this toxin entered the body of this previously perfectly healthy boy and what the nature of this cellular poison could be, whether it was ingested in the form of bacteria or spoiled food, cannot now be proven. Perhaps it could have been revealed by a more careful study at the time of illness or immediately after death. The cause of death was rather hastily ascribed to "acute enterocolitis due to the eating of Ex-Lax tablets." Others have referred to this case as it is so on record, although a perusal of the original report shows that the cause and effect is by no means definitely established. The evidence submitted is the post hoc ergo propter hoc kind and therefore open to the just criticism that such observations merit.

I have included the rather detailed report of this unusual case of Cleeves only to prove my own arguments. I do not believe that there will be even a single colleague among my readers who will be willing to see in this case, any connection between phenolphthalein and the febrile hemorrhagic toxic effects described by Cleeves. Moreover, I am convinced that my colleagues who have used phenolphthalein on any number of occasions with absolute satisfaction read this article in America with the same criticisms that I have made

and confidently continue to prescribe phenolphthalein without hesitation.

The report of this fatal case appeared opportunely for Dr. F. J. Cullen, formerly the Director of the Federal Food and Drug Administration of the Department of Agriculture, in Washington, who is striving to restrict the public from the use of laxatives and other drugs, no matter how harmless they may be, when put up in the form of candy or chewing gum. As I mentioned before, I share entirely Dr. Cullen's viewpoint according to which it is a fact that there is no possible, logical excuse that patent medicines (specialties) should be put up in misleading candy form and should be available for sale to the public without differentiating medicine from candy. But I am sorry that in his fight for this principle, he declares war only on phenolphthalein and after citing all the incriminating data including the Cleeves case, he finally ends by stating that it is generally known that phenolphthalein has a well recognized injurious effect on the liver. The latter statement has no foundation in fact. No purpose will be achieved by exaggeration or distortion of the truth. One defeats the very aims desired to be attained by such methods.

This review will be incomplete if I should fail to mention the reliable observations which seemingly indicate that very occasionally certain individuals have an allergic hypersensitiveness to phenolphthalein. This hypersensitiveness usually manifests itself in a mild skin eruption (Abramowitz (10a), Wise and Abramowitz (10b), Ayres (10c), Corson and Sidlick (10d), Rosenbloom (10e), Ely (10f)). Such observations have been made since 1918 following the extensive investigations of Storm VanLeeuwen on allergy and asthma which stimulated further work of this sort in the United States. In later years reports of skin eruptions from phenolphthalein have appeared from various parts of Europe and recently our own Dermatologists have encountered instances of this sort which altogether may be considered rather rare and nothing more than a curiosity. These are considered idiosyncrasies and they are of no more significance than those idiosyncrasies brought on by berries, lobsters, sweet cream, pollen, chicken feathers, horse hair mattresses, etc., which certain individuals cannot tolerate. We also sometimes find patients who possess an idiosyncrasy to drugs like aspirin, bromides, digitalis, iodides, ipecac, and the antipyretics and analgesics, but who would even think of giving up these valuable drugs for that reason?

I owe this short critical review of the reports emphasizing the harmful effects of phenolphthalein to my colleagues and my conscience because I have been responsible for its world wide usage. I have no intention of showering phenolphthalein with undeserved praise. The many publications which have approved the use of this drug on the basis of innumerable and careful clinical observations support my contention that phenolphthalein is harmless. In view of the popularity of phenolphthalein this is really unnecessary, yet it is my desire that my colleagues should be convinced of the harmlessness of phenolphthalein, as a am. They should receive reports of the ill effects of this drug that are based on post hoc ergo propter hoc reasoning with scepticism and form their opinions based on their own experiences and on those of other reliable investigators, as befits independentiy thinking physicians.

SECTION II—*Experimental Physiology*

The Prophylactic Value of Gastric Mucin in the Therapy of Post-Operative Jejunal Ulcer:
An Experimental Study in Dogs

By

J. R. ORNDORFF, G. B. FAULEY

and

A. C. IVY*

CHICAGO, ILLINOIS

IN this paper, the authors will report the results obtained on the prevention of the occurrence of jejunal ulcer in dogs when operated according to the method of Exalto (1) and Mann and Williamson (2). This method involves an end-to-end gastro-jejunostomy, and the diversion of the pancreatic juice and bile into the last twelve inches of the ileum. This method was chosen, first, because from 95 to 100 per cent of dogs so operated develop jejunal ulcers, and second, because of this regularity of occurrence of ulcer, positive results obtained by a therapeutic procedure would have more significance. The prophylactic therapeutic agents employed were (a) gastric mucin, (b) alkalies, (c) a mixture of gastric mucin, alkalies and raw ground pancreas. Experiments have also been made in which the effect of gastric mucin and raw ground pancreas on the healing of an ulcer after its development was studied. The results of gastric analyses, hemoglobin and plasma bicarbonate determinations will be reported.

CONTROL EXPERIMENTS

It should be borne in mind that the diversion of the bile and pancreatic juice into the lower ileum *per se* produces a marked disturbance of digestion and the large majority of animals so operated lose considerable weight and require special care in regard to hygiene and nursing.

The animals in this series of studies were kept in cages usually containing excelsior bedding and were fed a diet of ground meat, either fresh or brought to the boiling point (chiefly the latter) as preferred by the individual animal, and milk. The animals were fed three times daily, some eating all the food within a short period, others eating throughout the day. The stomach tube was not used on any of the control dogs, but it was frequently used to administer therapy in the treated dogs.

Mann (2) reported the jejunal ulcers develop in dogs prepared by his method in from three weeks to four months post-operatively, the average time being about one month. He did not cite specific data, but he stated that from 90 to 95 per cent of the dogs develop ulcer. Morton (3) observed that all of twenty dogs similarly operated developed ulcer in from fourteen days to four months. Owings and Smith (4) found that ulcers occurred in all of ten dogs in from forty-two to 428 days, the average being 118 days. L. R. Dragstedt (5) found that ulcers occurred in six dogs in from twenty-six to sixty-one days, the average being thirty-nine days.

Since the hygiene and diet of dogs operated on according to the method employed may be of some significance, it was thought best to operate a control series and determine the occurrence of jejunal ulcer on our diet and under our laboratory conditions. We should add that in every dog operated the duodenum was anastomosed to the ileum 12 to 15 cm. proximal to the ileo-cecal sphincter.

Accordingly, forty-two healthy dogs were operated and used for untreated controls. (If the dogs are prepared properly before the operation, the immediate mortality of the operation is practically zero). In all of the forty-two untreated control dogs, jejunal ulcer was found at death in from fourteen to 120 days post-operatively, the average being seventy-eight days.

In order to use the data obtained on the control dogs more effectively and to compare, *vide infra*, the data obtained in the control group with that of the treated groups, curves A and B in Figure 1 were constructed. Curve A represents the percentage survival-time curve of the forty-two untreated control dogs with a Mann-Williamson operation, all dying with ulcer but not always directly due to the complications of ulcer. For example, referring to Curve A, it will be noted that 50% of the dogs had died with ulcer at 11 weeks. Curve B represents the time of diagnosis of ulcer in twenty-two of the dogs. For example, referring to Curve B, it will be noted that 50% of the dogs had developed ulcer at 7 weeks. The diagnosis was made on the basis of "tarry stools" or gross blood in the gastric analysis; in eight the diagnosis of ulcer was confirmed by surgical exploration. These curves will be used later to interpret the data or the prophylactic effectiveness of the therapeutic measure employed.

GASTRIC SECRETORY AND BLOOD STUDIES

It was obviously important to possess knowledge concerning the effect of the operation on gastric secretion and emptying time. In addition, since the alkaline juices were being passed into the ileum near the colon,

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago, Illinois.

Submitted October 10, 1935.

they would be more subject to loss from the body. Thus, it was considered important to follow the alkaline reserve in a group of the animals. Hemoglobin and hematocrit determinations were also made.

McCann (6) seems to have made the only study to determine whether or not gastric acidity is influenced by the Exalto-Mann-Williamson operation, or to determine whether the ulcer is due to an acid chyme of normal or hypernormal quantity and quality. By a method of fractional gastric analysis, he measured the effect of the Mann-Williamson operation on the acidity of the gastric contents during digestive activity and during rest. He reported that there was no essential alteration in the character of the curves of the acidity of the gastric contents in response to the test meal after the Mann-Williamson operation, and concluded that "these ulcers have occurred with the passage of chyme of normal acidity." Yet, during the stage of ulcer formation, he noted the development of an increased quantity of resting basal secretion, and a post-operative impediment to emptying. Morton (3) also found by roentgenologic study that there was a slight stasis during the first two weeks after operation and that this subsequently increased. We considered McCann's work incomplete and desired further information.

Outline of methods. Dogs in this experiment were carried through three stages, namely, before, during, and after experimental induction of jejunal ulcers. In the first stage, control values were established for the following tests: the acidity of the gastric contents in response to a meal, the carbon dioxide combining power of the blood plasma, the red corpuscle and plasma volume, and the weight. The dogs were then subjected to the operation, which produces ulcer in 95 per cent or more of dogs, and were thus in the stage during ulcer formation. During this stage, further determinations of the values for the above tests were made. After the diagnosis of ulcer was made, either by surgical exploration, or clinical and laboratory observations, the dogs were in stage 3, or that after development of ulcer.

The various determinations were continued during the stage, in which *treatment was given.* Complete autopsy records were made at death or after etherization.

Explanation of experimental methods. The acidity of the gastric contents after a standard meal was determined by withdrawing through a large stomach tube a sample of gastric contents, at 2, 4, and 6 hours, or longer, after the feeding. The standard meal consisted of 200 c.c. milk, 100 gms. of finely ground meat and 50 gms. of finely ground raw pancreas. The test meal was always given after 10 hours of fasting to insure an empty stomach, *i.e.*, in the morning at eight o'clock. Free acid was determined by titrating against N/40 NaOH using dimethylaminoazobenzene as an indicator, and total acid by using phenolphthalein as an indicator. The response to the meal before operation was determined on 4 to 8 different, generally consecutive, days. The carbon dioxide combining power of the blood plasma was determined by the Van Slyke method. The red corpuscle count and plasma volumes were determined from the hematocrit reading made on the blood drawn for the carbon dioxide determination. The body weight was recorded at various times throughout the entire experimental period.

The operation was then performed, and from 10 to 12 days of post-operative convalescense were allowed before the daily test meals and aspiration of samples were resumed.

During the period of treatment, the acidity of the gastric contents in response to the test meal was recorded in the following manner. The 7:00 a. m. and subsequent mucin feedings were omitted; the meal was fed at 8:00 a. m., and aspiration of samples of stomach contents made at 10:00 a. m., 12:00 noon, and 2:00 p. m. Following the last aspiration, unless others were made, the dog was given the regular mucin-alkalie-raw pancreas feeding, and the cooked meat, and the schedule of three or four times daily feedings was recommenced.

During the control period before operation, aspiration was difficult, due to the lack of appreciable fluidity of the gastric contents. The stomach emptied between four and six hours after the meal. After the operation, however, all aspirations were easily accomplished and were productive of large amounts of non-viscous fluid containing a heavy suspension of fine particles. Over 200 c.c. could often be aspirated at 4 hours, and most always at 6 hours.

TABLE I

Averages of All Dogs

	Average Acidity

3. After ulcer diagnosed a. At Exploration	.056	.150	.203	.372	.394	.378
b. By Observation	.036	.100	.149	.320	.353	.340

Weight loss and appetite. During the post-operative period, the dogs manifested marked polyphagia, eating very rapidly much larger quantities than normal dogs of the same size. We presented all the food they could eat. However, the dogs lost on the average one-third (31 per cent) of their body weight between the time of the Mann-Williamson operation and autopsy. Eighty-four per cent of this loss had occurred by the time the diagnosis of ulcer had been made. Forty-five per cent was in the first 17 days after operation, which was 35 days before the average time of development of ulcer and was 7 days before the earliest ulcer formed in this group, which was one diagnosed by exploratory at 24 days. Thus, one-half the weight loss occurred in the first 2½ weeks, before any ulcers were present, and four-fifths by the time the ulcer had developed. This furnishes ample verification for the statement (7) that Mann-Williamson operated dogs have a marked nutritional disturbance.

Acidity averages. The acidity averages for all twenty-two dogs, based on 444 test meals and 2,664 titrations, are found in Table I, which is constructed on the basis of values for the individual dogs given in Tables II and III. The graphic representations of curves for these average values (Figure 2) show more or less post-operative increase in both free and total acidity at each of the three aspirations during the 6 hour period of observation. A relatively higher 2 hour free acidity distinguished the post-operative free acid curve from the closely parallel control.

Post-operatively, the gastric contents have a higher total acidity, which continues for a greater period of time.

After diagnosis of ulcer by exploration (8 dogs, Table X), even though treatment was given, the average acidities, both free and total, were distinctly higher (Figure 2, Curve 3). This must have been due to the operation. The jejunotomy must have caused increased local irritation and consequently greater retention of secretion. In the dogs where ulcer was diagnosed by observation, and the treatment started,

the acid values are lower (Figure 1, Curve 4). The 6 hour acidities show the greatest differences; at this aspiration, the free acidity exceeds that of the control and of the post-operative periods.

Individual acidity averages. From a study of the individual dogs, it is evident that in each dog the secretion might post-operatively remain unchanged, or exhibit any one of four possible variations in gastric secretory response. About 50 per cent of our dogs showed a post-operative increase in both free and total acidity. Only one dog (No. 13) showed a post-operative fall in both free and total acidity.

The increased "continuous phase" of gastric secretion was very evident and marked which confirms Mc-Cann. This and the very evident fluidity of the gastric contents leads us to conclude that following the operation a greater volume of secretion was produced. This was true of every dog regardless of the acid values.

The results of the study of hemoglobin and hematocrit determinations revealed that an anemia does not appear until the ulcer starts to bleed. This was true without a single exception. This shows that anemia is not the cause of the ulcer. The response of the dog to therapy was directly reflected by a rise in hemoglobin and hematocrit. The hemoglobin would rise and remain high during the chronic stage of ulcer, until bleeding started again. This was true of all dogs shown in Table XI. Perforation would occur in the presence of normal hemoglobin and hematocrit values.

Observations on Plasma CO_2 Combining Power: The control values for the plasma bicarbonate reserve varied from 48 to 55 per cent. From one to six weeks post-operatively every dog showed a decrease in plasma alkaline reserve, the values ranging from 30 to 48. About one-third of the dogs showed a gradual decline, the others fluctuated considerably. When hemorrhage started the drop was increased. During the week before starting mucin-alkaline-pancreas therapy, the values ranged from 29 to 48, the average being 37. On therapy the plasma bicarbonate was increased to or above normal, none rising above 68. The plasma bicarbonate would then fall depending on the amount of hemorrhage; only one dog fell below normal, however.

No correlation existed between the post-operative rate of fall of blood alkaline reserve and the rate of development of ulcer, although these determinations were made primarily to detect such a correlation. Such a correlation might have been possible, if fluctuations had not occurred to the extent observed. These fluctuations may have been due to either variations in the amount of pancreatic and biliary alkalie lost in the feces or to variations in blood loss which was not determined accurately (in view of the diet accurate loss

of blood in the feces could not be determined) and daily.

DISCUSSION

Although the free and total acidity was more or less definitely increased in one-half the animals, the most striking finding resulting from the gastric analysis is the failure of the total acidity to fall at the six hour period, as in the controls, and the hypersecretion of fluid of high acidity. This did not occur just before the development of the ulcer, but after the operation, and was not affected by the presence of ulcer; nor was it materially influenced by our therapy. We believe that the varying degrees of hypernormal acidity observed in about one-half of the dogs was due chiefly to retention. But, the hypersecretion of fluid observed especially at 4 and 6 hours after the meal and which continued afterwards, as observed by McCann, is of special interest and we believe bears on the etiology of the ulcer that results.

TABLE IV

Effect of Gastric Mucin and Alkalies on the Rate of Gastric Emptying Time. (Constituents of each meal are given in the text)

	Emptying time average of 4 or more tests			
Dog	Meal 1	Meal 2	Meal 3	Meal 4
I	4 hr 40 m	4 hr	4 hr	3 hr 30 m
II	4 hr 25 m	4 hr	4 hr	3 hr 40 m
III	4 hr 45 m	4 hr 5 m	4 hr	3 hr 40 m
IV	4 hr 15 m	4 hr	3 hr 50 m	3 hr 30 m

A discussion of the quality of the excessive fluid secretion and the mechanisms concerned in its formation is hardly warranted in this paper (see Ivy, ref. 8), but preliminary studies indicate that it is not materially influenced by relatively large doses of atropine. If this proves to be correct, it means that the mechanism concerned is not one of the normal mechanisms for gastric secretion in the dog, all of which are depressed by atropine. The most likely hypothesis is that the irritation of the upper intestinal mucosa may result in the elaboration of histamine-like substances which on absorption stimulate gastric secretion of HCl and fluid, and prolong the intestinal phase—an abnormal mechanism that would not be influenced by atropine except in toxic doses.

SUMMARY

1. Following the Mann-Williamson operation for duodenal drainage, there occurs an increase in both free and total average acidities in about one-half of the animals. In the others the acidity is not significantly altered. Gastric retention is present after the Mann-Williamson operation and is at least partly responsible for the early increase in free acidity. A marked increase in the intestinal phase of gastric secretion and in the continuous secretion occurs which unbuffered has a deleterious action to the especially susceptible jejunal mucosa (6, 7). There is no correlation between the time of ulcer appearance and the acidity. The nutritional or digestive disturbance in Mann-Williamson dogs is severe as shown by the excessive weight loss before development of ulcer. The acidity rises above the original post-operative level after exploratory diagnosis of jejunal ulcer and institution of gastric mucin treatment. The acidity falls below the original post-operative level after clinical and laboratory diagnosis of jejunal ulcer and institution of mucin and alkali treatment, but the change is not marked. The observations recorded on plasma bicarbonate reserve and on anemia in the Mann-Williamson preparation show that these factors play no definite etiologic *rôle*.

EFFECT OF GASTRIC MUCIN AND ALKALIES ON THE GASTRIC EMPTYING TIME OF DOGS

It was pertinent to these studies to obtain some idea of the effect of gastric mucin and alkalies on the emptying time of the stomach in the dog. It was shown that when gastric mucin was mixed with milk and then the milk clotted with rennin the resulting clot was less firm. This effect of mucin should, of course, facilitate the evacuation of milk from the stomach. This effect of mucin on the clot is shown by many substances, saliva, malted milk, certain mineral salts, etc.

Four normal dogs were selected and trained to lie quietly on the fluoroscopic table. The emptying time to the following test meals was followed: Meal 1: 150 c.c. milk, 25 gm. of finely ground meat, 30 gm. peptone and 35 gm. of barium sulphate. Meal 2: Same as Meal 1, except 30 gm. gastric mucin was substituted for the peptone. Meal 3: Same as Meal 1, except 1 gm. each of calcium carbonate and sodium bicarbonate were added. Meal 4: Same as Meal 3, except 2 gm. of each of the alkalis were used.

TABLE V

Showing the Effect of Gastric Mucin on the Incidence of Jejunal Ulcer After the Method of Exalto, Mann and Williamson. (Incidence of ulcer in these dogs is from 95 to 100%, the latter figure being obtained in control group of 42 dogs)

	Stock diet (see text)

22	2, b.i.d.	None	52	Explored at 12 months; no ulcer. Taken off mucin. Died of ulcer in 3 months.
16		6 had ulcer	Avg. 16 wk.	Occurrence of ulcer, 37%. Curve A. Prophylactic value, 35+%.

First four dogs omitted because they received only 0.50 oz. of mucin t.i.d., all dying of ulcer in from 4 to 11 weeks. Dog 8 and 15 omitted because they died without ulcer at 3 and 4 weeks post-operatively. + Calculated by Curve B, figure 1, the prophylactic value is 53%.

One gram of calcium carbonate and sodium bicarbonate each mixed had the same acid buffering value as 30 gm. of the mucin used.

The results are shown in Table IV. The results are obvious and require no discussion.

TABLE VI

Showing Occurrence of Ulcer in Mann-Williamson Dogs on Alkalies. (The doses of alkalies were equal to or greater than the buffering value of mucin given in other series)

Dog	Duration	Ulcer Incidence	Remarks
I	16 weeks	Two jejunal ulcers present. One perforated into omentum 2 cm. in diameter.	Diagnosis of ulcer made at end of 13th wk. Lost ½ body weight.
II	25 weeks	One large indurated jejunal ulcer. Non-perforated.	Lost ½ body weight. Hemorrhage.
III	7 weeks	Two jejunal ulcers present.	Lost ½ body weight. Hemorrhage.
IV	7 weeks	No ulcer present. Cause of death marked enteritis, of unknown cause.	Blood in stool. Lost ⅓ body weight.
V	9 weeks	Acute jejunal ulcer 1 cm. in diameter present.	Lost ½ body weight. Hemorrhage.
VI	11 weeks	Two jejunal ulcers present. One perforating ulcer 1 cm. in diameter which occurred approximately 3 cm. from the anastomosis.	Lost ⅓ body weight.

Alkali Therapy Used

Dogs I, II, III and IV received 2 grams of sodium bicarbonate and 2 grams of calcium carbonate (total of 4 grams) twice a day throughout the entire course.

Dog V received 4 grams of the mixed alkalies twice a day for the first six weeks, then 2 grams of the mixed alkalies twice a day for the last three weeks.

Dog VI received 4 grams of the mixed alkalies twice a day for the first five weeks, then 2 grams of the mixed alkalies twice daily for the last six weeks.

GROUP TREATED WITH GASTRIC MUCIN

In Table V are shown the data on 22 dogs which were operated and then placed on gastric mucin several days later. Since it was not known at first what dose of mucin to use, it is to be noted that the dose was varied somewhat. Of the 22 dogs on mucin, only 6 (or 45 per cent) developed ulcer. If the first four dogs on the small dose of mucin are omitted, and two which died without ulcer at 3 or 4 weeks post-operatively, then ulcer occurred in only 6 out of 16 animals, or 37 per cent. The average length of life of the 6 dogs dying with ulcer is 82 days. The average length of life of the 10 dogs that did not develop ulcer is 131 days. All the 10 dogs, except 3, died without ulcer within a period during which ulcer developed in the control dogs. So, gastric mucin administration in the larger doses kept 10 dogs, or 63 per cent, free from ulcer for an average of 131 days. Life was continued beyond the average for the control group in only 7 dogs. Thus it becomes evident that the operation *per se* in the presence of therapy has a latent mortality of 63 per cent. That is, dogs so operated may live a number of weeks and *die without a jejunal ulcer when given gastric mucin.* This mortality is due chiefly in our experience to a marked disturbance of digestion intercurrent infection, adhesions, intra-abdominal strangulation, etc.

A mathematical treatment of the data in this group is necessary because some dogs may live a considerable period without developing ulcer and others may have developed ulcer had they lived longer. Hence, it was necessary to determine in the case of each dog that died without ulcer, the chance that ulcer should have been present at death. For example, Dog 5, Table V, died at ten weeks without ulcer. Turning to Curve A, Figure 1, it is seen that at ten weeks, the chance of the dog having an ulcer at death is 40 per cent. When the chance is determined for each of the sixteen dogs, assigning zero prophylaxis to the ulcer dogs, and then totaled and averaged, it is found to be 35 per cent, which obviously is more nearly the correct evaluation of the prophylactic effectiveness of mucin *in this group of animals* than the 63 per cent value indicated on a superficial study of Table V. However, it is believed that the figure of 35 per cent represents a minimum figure, since if the truer Curve B of Figure 1 were used instead of Curve A, a larger per cent than 35 would be obtained, namely 53 per cent. The most striking result, however, is shown by the records of dogs 21 and 22. These dogs survived one year without developing an ulcer and then died of ulcer after withdrawing mucin therapy.

It is concluded that gastric mucin when fed in adequate amounts at least delays the onset of ulcer in some dogs and prevents its development in an occasional dog.

ALKALIES

To determine if gastric mucin was producing its effect by buffering free acid, alkali was administered in the food (twice daily) in quantities sufficient to equal at least the buffering value of the mucin given in the other groups. Except as noted in Table VI, 2 grams of sodium bicarbonate and 2 grams of calcium carbonate (total, 4 grams) twice daily was the dose of alkali used. No attempt was made to maintain the gastric contents neutral, as this was not the object of

+ Calculated by Curve C, prophylactic value is 70%.

++ Average does not mean much because of dogs 7 and 11.

this group of six experiments. It might be pointed out that one gram each of the alkalies used twice daily is sufficient to neutralize 638 c.c. of N/10 HCl. The results are recorded in Table VI.

Five of the six dogs died with ulcer, one of enteritis. The average survival time was about two weeks longer than that of the control dogs. It is to be noted that Strikingly, the survival time of the four dogs dying with ulcer is 175 days. This is twice the survival time of the control group. The record of dog 11 is especially striking. Dog 7 may be one of the rare dogs, which after this operation, never develops an ulcer. Yet we diagnosed clinically an ulcer in this dog, before raw pancreas was given.

one of the dogs survived longer than the maximum control time. More dogs were not used in this series because it has been reported that the administration of alkalies does not prevent the development of ulcers in Mann-Williamson dogs by Meyer and Rubin (9), and by Doctor Mann (personal communication). The attempt to maintain complete neutralization is practically impossible in the dog. These results when viewed in the light of the preceding data strongly indicate that mucin does not act to prevent ulcer primarily through its capacity to buffer free acid.

GASTRIC MUCIN—ALKALI—RAW GROUND PANCREAS

Since the authors were interested chiefly in discovering some way to prevent the development of ulcer in dogs operated by the Mann-Williamson method and in keeping such dogs in good nutritional condition, and since gastric mucin will not prevent ulcer from occurring in all such dogs, regardless of the amount of mucin given twice or three times daily, it was decided to add other possible therapeutic procedures to the mucin regime.

A group of nineteen dogs (Table VII) was operated and placed on the regular diet, including 30 grams of gastric mucin, one gram each of sodium bicarbonate and calcium carbonate thrice daily and 200 grams of raw ground pancreas twice daily. The alkali was given to combat the acidosis and for its neutralizing value. Sodium bicarbonate was used regardless of the fact that it tends to stimulate acid production in the dog (11). Raw pancreas was added to improve digestion, if possible.

That the raw ground pancreas improved the nutrition of some of these animals was not discovered until after the first nine dogs had been operated for some time. So the first nine dogs in Table VII did not receive raw pancreas until some time (1-2 months) after they were operated. Four of the nineteen dogs were discarded because they died of pneumonia at 3 and 4 weeks post-operatively. Of the fifteen animals, ulcer developed in only five, or 33 per cent. The average survival period for the fifteen dogs is very high because two of the dogs are still alive at over three years.

When the data in Table VII are treated by using Curve A in Figure 1, the result obtained indicates that the prophylactic value of the mucin-alkali-raw pancreas regime is 57 per cent and not 66 per cent as indicated by a superficial study of Table VII; using Curve B, the prophylactic value is 70%. These figures are too high because dogs 2, 3 and 12 developed ulcer and according to the curves receive a prophylactic value of 100 per cent, which is due to the fact that they survived longer than the maximum time of the controls without having ulcer by clinical and post-mortem diagnosis.

By comparing the data obtained from the mucin group (Table V) with the data from the mucin-alkali-raw pancreas group (Table VII), one is forced to conclude that the latter therapy is more effective. In this connection it should be realized that the mathematical treatment is not perfect and is only very roughly approximate. In order to arrive at more accurate results, more animals must be used in each group. However, it should be appreciated that experiments of this nature are subject to *very rigorous control*, are expensive and the animals require a large amount of attention, and the inclusion of a larger

number of animals in each group would not be indicated unless the results were less definite than they are.

SUMMARY

It is evident from the results that the administration of gastric mucin, or gastric mucin-alkali and raw pancreas is of prophylactic value in experimental post-operative jejunal ulcer which develops when pancreatic juice and bile are drained into the last few inches of the ileum; but neither therapy is effective in all animals. It can be stated that the addition of raw pancreas to the gastric mucin management is of value in that it improves the nutrition of the animals; but it cannot be stated that the addition of alkali to gastric mucin is of advantage until results have been obtained on a group given gastric mucin and alkalies and on another group given alkalis and raw pancreas (see Tables VIII and IX).

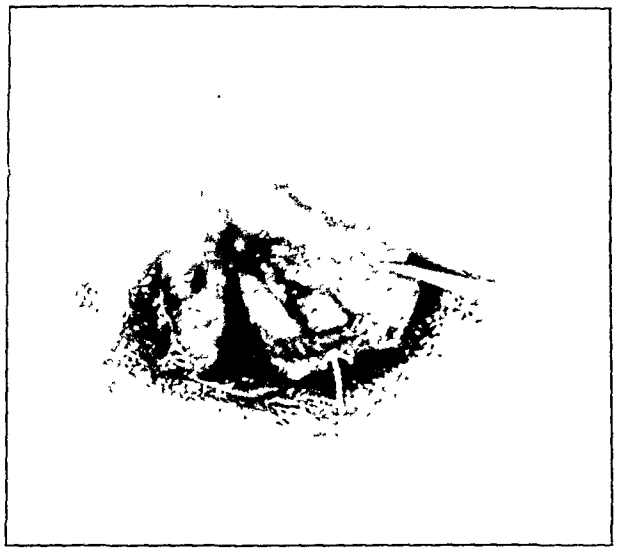
ATTEMPTS TO OBTAIN HEALING OF EXPERIMENTAL JEJUNAL ULCER IN DOGS

Experiments have been performed in an attempt to determine if healing of the jejunal ulcer may be induced by the mucin-alkali-raw pancreas therapy. This problem was not attacked first because it was realized that it would be easier to obtain a prophylactic than a healing effect. This is true because generally by the time these animals develop an ulcer, their nutritional condition is poor and difficult to control.

The experiments were planned as follows: The operation was performed. The animal was then placed on the regular diet with which 100 grams of raw pancreas was

TABLE X

Preliminary Studies on Healing of Ulcer Under Therapy. (In the experiments the ulcer was clinically suspected as being present. Exploratory operation was performed. Photograph of ulcer was taken, if one was present; if not, an artificial ulcer was made)



Dog No.	Ulcer found by exploration	% loss of weight between M. W. operation and exploratory	Observations on healing after therapy	Remarks
1	5 weeks. 6x8 mm. involving muscle wall.	30	Ulcer perforated 48 hrs. later.	*This finding caused us to begin therapy on day of operation.* Extension of ulcer probably due to unbuffered post-operative secretion.
2	5.5 weeks. 3 mm. dia. mucosa only involved.	None	Healing in 15 days.	Dog was pregnant. Histological examination showed mucosal defect not completely regenerated.
3	6 weeks. 4x5 mm. muscle layer visible.	17	Healing in 3 wks. Specimen resected by operation. New anastomosis made.	Gained 13% of wt. on therapy in 3 wks. Dog lived 4 months on therapy after resection. Died without ulcer. Histological exam. of resected specimen showed mucosa had covered defect.
4	5 weeks. 2x3 mm. involved mucosa. Linear abrasions of mucosa.	18	Healing in 6 wks. specimen resected new anast. made.	Gained 12% wt. on therapy. Dog lived 16 wks. on therapy after resection. Hist. exam. revealed healing of defect at 16 wks. Dog had chronic indurated ulcer. Was sacrificed. Loss of weight, 25%.
5	6 weeks. No ulcer found. Ulcer 5x4 *made by* excision.	16	42 da. later, ulcer was found to be healed.	Therapy resulted in healing of artificial ulcer. Dog sacrificed. Gained some weight on therapy.
6 W.	6 weeks. 5x3 mm. Muscle layer visible.	20	25 days later ulcer healed.	Distinct scarring of mucosa visible. Regeneration of mucosa incomplete. Dog gained wt. on therapy.
7	7 weeks. 3x5 mm. ulcer.	20	29 da. later spec. ulcer had healed.	Dog died from pneumonia. Dog remained at same wt. on therapy. Histological examination shows defect covered, but regeneration incomplete.
8	3.5 weeks. No ulcer found. 3x5 mm. ulcer made by excision.	25	49 da. later spec. resected. Ulcer had healed.	Could find no ulcer and were uncertain concerning scar in mucosa.

TABLE XI

Observation on Healing of Ulcer by Institution of Therapy (Ulcer Well Advanced as Indicated by Blood Loss)

23	9	11		—21	6	None	Perforated ulcer.
24*	6	33		+55	52	Complete	After 52 wks. therapy was removed. Dog died 50 wks. later of indurated perforated ulcer, loss of weight, 12%.

Dog 18, 21 and 22 died at 9, 6, & 22 died of causes not related to ulcer.

Photograph 1 was made of the ulcer of dog 1, Table 10, at an exploratory operation.

mixed. This mixture was fed three times daily. When the presence of ulcer was diagnosed clinically, the animal was explored, a photograph of the ulcer being made. This was done on eight dogs in this series. On the afternoon

Photograph 2 was made of the ulcer of dog 1, Table 10, 48 hours after the exploratory operation. We believe the marked extension of the ulcer and its perforation was due to the unbuffered gastric secretion which is frequently formed post-operatively after operations on the stomach and upper abdominal viscera.

Photograph 3. This photograph was made at the exploratory operation in dog 2, Table 10. It involved only the mucosa and was found to be healed after 15 days on therapy.

of the same day, mucin was administered by stomach tube, and thereafter *four times a day* in 30 gram doses at 7:00 a. m., 12:00 noon, 5:00 p. m. and 10:00 p.m. The pre-operative diet was instituted again on the second or third day post-operative, the mucin being continued four times a day.

The administration of gastric mucin was started on the same day as the exploratory operation because of the following observation: Dog 1, Table X, was explored on a Saturday morning. A jejunal ulcer, six by eight mm. was found and photographed (Photograph 1) and the animal closed. On Sunday, the animal was given water. Monday morning at 8:00 a. m., the animal died. Autopsy revealed a perforated ulcer with blood in the peritoneal cavity and bowel. On opening the jejunum, it was found that the ulcer had perforated, the perforation measuring six by eight mm., and that the lesion in the mucosa had extended until the ulcer now measured fourteen by twenty-six mm. This marked extension of the ulcer had occurred within forty-eight hours, during which time nothing but water had been allowed. The blood supply had not been disturbed, since the ulcer was on the posterior wall and the exploratory incision was made in the anterior wall. Therefore, we should explain the rapid extension of the ulcer as due to the unbuffered post-anesthetic and operative secretion

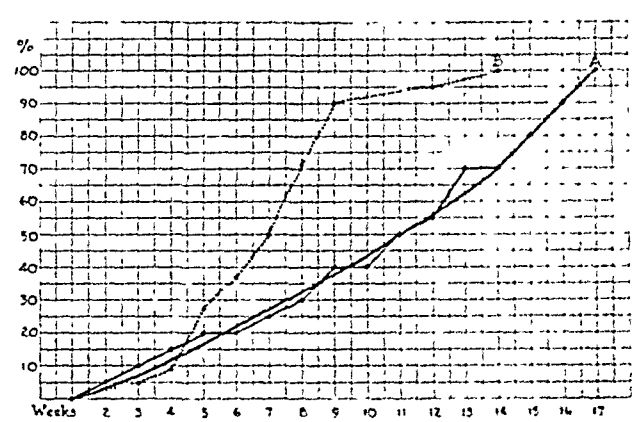

Fig. 1. Curve A represents the percentage survival-time of the 42 untreated control dogs. Curve B represents the percentage diagnosis-time of ulcer in 22 of the dogs; for example, 50% of the dogs had ulcer at 7 weeks.

of gastric juice, which commonly occurs in the dog, acting on a specially susceptible jejunal mucosa.

In Table X are recorded the results of a preliminary study on 8 dogs in which the dogs were explored. Ulcers were diagnosed clinically prior to the exploratory in all dogs but dog 8. One diagnosis was missed, namely, in dog 5. The results show that the healing of two artificially produced ulcers and healing of all spontaneously occurring ulcers was obtained except in one dog.

Encouraged by these results, which bear only on the healing of very early ulcers, we proceeded to study another group in which the ulcer was permitted to progress until the clinical and laboratory evidences of ulcer were much more pronounced. We were certain that the foregoing results applied only to very early lesions, because of the course of some of the animals after the resection operation and particularly because in dog 4 we found that the original ulcer had healed on therapy and a new ulcer 2 cm. distant had appeared. (We have no adequate explanation for the latter observation). Accordingly, observations were made on thirteen dogs. By referring to Table XI, it will be observed that healing of the ulcer was obtained in only two of the thirteen (15%) animals. Although the average survival time after therapy was started is only 14 weeks, it is to be noted that the survival time was extended beyond the maximum control time of 17 weeks in 4, or 30%, (dogs 13, 16, 19 and 24). However, in nine, or 69%, the survival time was extended beyond the eleven week average of the control group.

SUMMARY

This evidence again testifies that the therapy was of value, in that it caused healing in two dogs and delayed lethal hemorrhage and perforation in some but not all of the others. Since these dogs received raw ground pancreas after the Mann-Williamson operation was performed, and developed ulcer in the same time as the controls, it is evident that raw ground pancreas alone has little direct prophylactic value.

LIVER HISTOLOGY

A histologic study of the liver was made in many of these animals because of the occurrence of the spontaneous duodenal ulcer in animals subjected to operative procedures which cause liver damage (10). No changes were found. (Dr. Reymont found no changes in liver function as revealed by ordinary liver function tests).

GENERAL SUMMARY

The prophylactic value of gastric mucin therapy and of gastric mucin-alkali-raw ground pancreas therapy on the post-operative jejunal ulcer (Exalto-Mann-Williamson) that occurs in 95 to 100 per cent of dogs after diversion of the pancreatic juice and bile into the lower ileum has been studied in a relatively large number of animals. We cannot conceive of a more severe test of the therapeutic value of any therapy for "peptic ulcer" than that provided by the "Mann-Williamson preparation." The ulcer which occurs in these animals is believed to be quite analogous to the jejunal ulcer which occurs after gastro-enterostomy in man. The results obtained show that both therapies have a definite prophylactic value, the latter being the more effective. However, it is believed that these therapies are chiefly palliative and do not attack directly the chief etiologic agent of the ulcer studied, which would appear from the results of our gastric analyses, and the studies of others, to be a hypernormal (also continuous) (increase in quantity) secretion of gastric juice, which, because of the diversion of pancreatic juice and bile is not subjected to adequate neutralization in the jejunum, the mucosa of which is susceptible to acid irritation. That a nutritional factor is etiologically concerned cannot be doubted from a careful study of our records, which, however, at the same time, will show that it is not the only etiologic factor concerned. We believe that if one should be able to devise ways to prevent these two factors from operating, the occurrence of ulcer in the Mann-Williamson preparation would be prevented.

WHEN trying to appraise the condition of any organ, such as liver or kidney, which has many functions, the physician can hardly hope to find a single test which will always be trustworthy and helpful, especially for the detection of slight injuries. Actually he should search with several tests, each designed to probe the functional capacity of some one set of cells in the organ.

Is it not surprising then that we physicians have so long remained content with but one test for gastric function, namely, the titration of hydrochloric acid? We have stuck to this one test in spite of the fact that for years it has been known that there are three main types of secreting cells in the mucous membrane lining the stomach: (1) the parietal cells, which produce little besides hydrochloric acid and water; (2) the chief cells, which produce pepsin and probably other ferments, and (3) the mucoid cells, which produce mucus and perhaps some of the so-called diluting fluid of the stomach.

If the estimation of gastric acidity had been of great and decisive value in the making of diagnoses, one could more easily understand our single-hearted devotion to this one test, and our neglect of other possible tests of gastric function, but actually, in practice, it is rarely of pathognomonic value.

To be sure, a considerable amount of clinical work has been done with pepsin, but unfortunately, the methods used by the earlier workers were crude; usually, the number of cases studies was not sufficient for satisfactory statistical analysis, and seldom was the concentration of pepsin measured in such terms that the results of one investigator could be compared with the results of another.

Because of these defects in the literature on pepsin we shall not attempt to review work already done but shall proceed to a description of our own efforts to gain answers to the many questions that arose in our minds. In beginning this work we wished not only to contribute something to the physiology of gastric secretion but we hoped that estimations of pepsin in human gastric juice might in some cases prove to be of more value to the clinician than the measurements of acidity have been.

Two preliminary papers were published in 1933 (1, 2). We are now able to make a final report on the results of the study of a much larger series of cases. The present paper deals with physiologic considerations, while two others will deal with alterations of pepsin in the presence of disease.

We first had to secure answers to such important basic questions as: What is the best method of securing juice for analyses of pepsin? What is the variability to be expected in repeated tests on one person, and what are the limits of normal secretion? How much does age or sex influence the secretion? To what extent are acid and pepsin secreted together?

The answers given here are based on a study of 5378 analyses of gastric contents; 4255 of these were made on samples removed from men and 1123 on samples removed from women. There were 1381 samples of juice obtained after an Ewald type of test meal, 762 were removed after a night's fast, and 3232 were removed after the injection of histamine.

We do not have as many data from normal persons as we would like, but, fortunately, there are reasons for believing that one can learn much about the variations in the secretion of pepsin in normal persons from a study of patients with gastric or duodenal lesions. Tests have shown that with both pepsin and acid the presence of a lesion may raise or lower the mean, but aside from this shift, the characteristics of the distribution are not affected, and the effects of age and sex are much the same as in normal persons.

TECHNIC

In this paper, for the sake of convenience and brevity, we will speak of test-meal juice, fasting juice, and histamine juice: Test-meal juice was obtained one hour after the ingestion of eight arrowroot cookies and 400 c.c. of water. Fasting juice was obtained in the morning before breakfast. To obtain histamine juice, the drug was injected in doses corresponding to 0.1 mg. for each kilogram of body weight. Beginning ten minutes after the injection, the gastric contents were aspirated as completely as possible every ten minutes until six samples were obtained. A small-bore Sawyer tube was used.

To determine the concentration of free acid, titration was done in the usual way with Töpfer's reagent. Wherever acid is mentioned in this paper the figures represent free acidity.

In measuring the concentration of pepsin we used a modification of the Gates, Gilman and Cowgill method, described by us elsewhere (1). The unit of measurement was established arbitrarily by Gilman and Cowgill as

*Studies I and II of this series bore the general title, "Studies of Gastric Pepsin."

Submitted September 16, 1935.

representing the proteolytic activity of a 1 per cent solution of a 1:10,000 commercial solution of pepsin.

Test meal juice.—Table I shows the characteristics of test-meal juice as obtained from ninety-six apparently normal men and sixty-three apparently normal women. In 1933 (1), we reported that in most normal men and women, the concentration of pepsin in test-meal juice is less than 500 units, with a mean of 145 units and a median of 135 units. With the data now added, the mean for men is found to be 238 and the median 151 units. For women the corresponding figures were 190 and 110 units. The markedly skewed J-type of percentage distribution can be visualized from Figure 1.

This great skewness or asymmetry of the distributions representing concentration of pepsin is due partly to the fact that the concentration of a ferment varies

Fasting juice.—Table I shows concentrations of pepsin and hydrochloric acid in fasting juice obtained from seventy-seven apparently normal men and fifty-one apparently normal women. It will be seen that the mean acid concentration is lower than that found in test-meal juice, and achlohydria is met with more often. On the other hand, the concentration of pepsin is considerably greater in fasting juice than in test-meal juice. In the case of men, the mean was 371 units, and the median, 190 units. The corresponding figures for women were 256 and 120 units. The range was from 0 to 8500 units.

Histamine juice.—In Table I will be found mean and median values for concentrations of acid and pepsin and volume of juice in the six samples removed at ten-minute intervals after the injection of histamine. It will there be seen that the *concentration* of

**Secreted in the first thirty minutes.

as the square of the amount of substrate digested. However, even when square roots of the values were plotted, the distributions were still somewhat skewed. This may perhaps be explained by assuming, what we have good reasons for believing is true, that our human material is not homogeneous in regard to gastric secretion but consists of at least two groups, one made up of persons with normal concentrations of acid and pepsin and the other made up of persons with abnormally high concentrations. Our impression is that high concentrations are commonly found in a tense type of person whose secretory mechanisms are overly reactive to nervous stimulation. It is conceivable that if, by some anthropologic measurement, we could recognize these two types of persons and segregate data from them, the two distributions representing concentrations of pepsin would be symmetrical.

It will be obvious that, with such skewed distributions, a mean is of little value as an index of central tendency and hence it is that we have depended more on the median or mid-value.

pepsin rose for the first twenty minutes and then fell for thirty minutes to rise again the last ten minutes. The *concentration* of acid and the volume of juice secreted rose together for the first thirty minutes and then fell. These observations agree with those made on animals, all showing that in juice obtained after injection of histamine, the apex of the curve representing concentration of pepsin comes earlier than that representing concentration of acid (Fig. 2).

Since many studies indicate that the acid of the stomach comes from the parietal cells at a constant concentration, which is determined by the osmotic pressure of the blood, the probability is that so long as there is any secreting mucous membrane left in the stomach the concentration of hydrochloric acid will be as nearly normal as dilution by other secretions will permit. Under such circumstances, it would seem that when one wants to get some idea of the extent of injury wrought in the stomach by disease, one should turn to a study of the *quantity* of acid secreted rather than its *concentration*. Similarly, the *quantity* of pepsin secreted in a unit of time might be of more

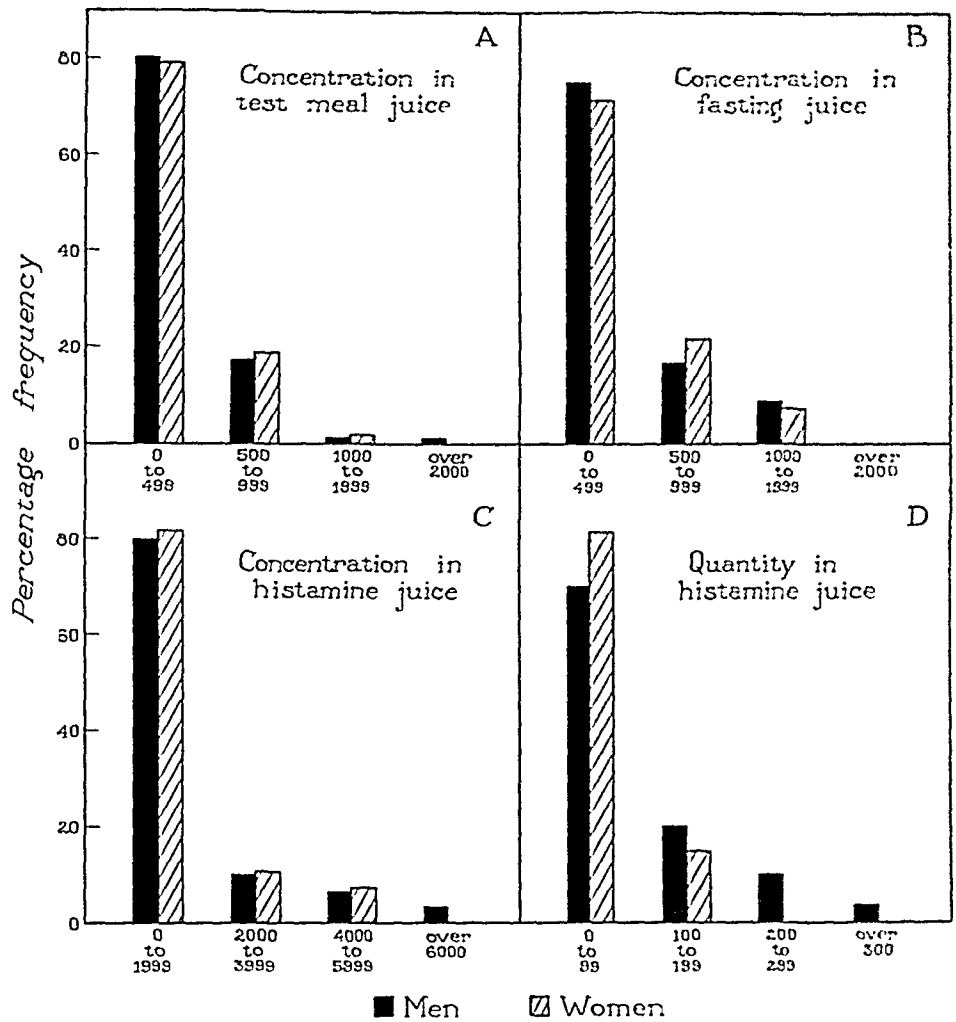

Fig. 1. Percentage frequency distributions showing pepsin values in gastric juice of normal persons. A, Concentration in test-meal juice; B, Concentration in fasting juice; C, Concentration at the peak of the curve of secretion of histamine juice; D, quantity of pepsin secreted in the first thirty minutes after the injection of histamine.

value than the figures for *concentration* in each of the six specimens.

As everyone knows, the quantity of any substance in a given sample of fluid is found by multiplying the figure expressing concentration by the figure expressing volume. Mean quantity of acid and mean quantity of pepsin in each ten-minute sample are shown graphically in Figure 3. The curves representing *quantities* of secretion closely resemble those showing *concentrations*, with the exception that the curve representing quantity of pepsin does not tip up at the end as does that representing concentration of pepsin.

Because, in histamine juice, most of the acid and pepsin is secreted in the first three ten-minute periods, we decided to use as convenient indices to the quantities of acid and pepsin secreted by a given stomach sums of the quantities of acid and pepsin respectively present in the first three samples. From Table I, it will be seen that the mean quantity of acid secreted in the first thirty minutes, expressed in terms of cubic centimeters of tenth-normal hydrochloric acid was 41.7 for men and 26.3 for women, the median value for the corresponding quantity of pepsin secreted in the first thirty minutes, expressed in terms of milligrams of Armour's 1:10,000 pepsin, was 340 for men and 310 for women.

The higher concentrations of pepsin met with in this study were found usually in histamine juice. The mean in normal men varied from 558 to 1610 units in the six ten-minute samples. In women it varied from 496 to 806 units. The corresponding range of the medians was from 420 to 1160 in men and from 285 to 660 in women. In 23 per cent of thirty-one apparently normal men and women we obtained pepsin readings of more than 2000 units in at least one of the six samples. The highest concentration found in apparently normal men and women after the injection of histamine was 4300 units. In 69 per cent of normal men and women the pepsin concentration in histamine juice was more than 500 units, the figure which we have chosen as the upper limit of normal for test-meal juice.

The question arose in our minds as to which would be the best of the six specimens to use if only one estimation of pepsin were to be made. Measurements of pepsin are time-consuming and often it might be desired to make only one such measurement on juice from each patient. From Figure 2, which shows the

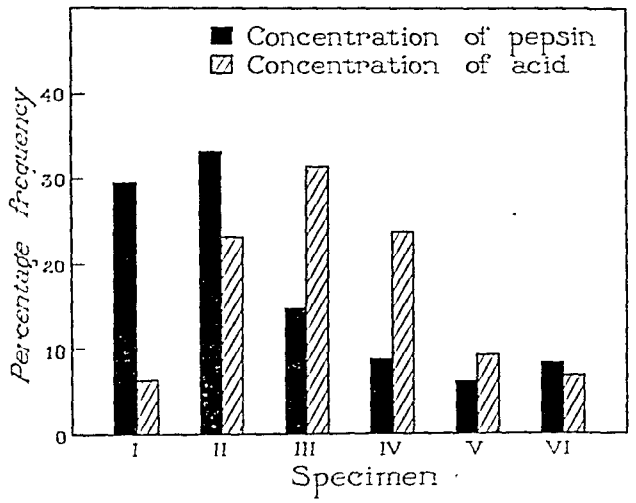

Fig. 2. Percentage frequency distributions of the highest concentration of acid and of pepsin in the six specimens of histimine juice.

frequency of occurrence of the highest concentration of acid and pepsin in the six samples, it appears that it is the second specimen which is the most likely to contain a large amount of pepsin. Still more representative perhaps would be a sample taken after pooling the first two or three specimens.

Another question is, does histamine stimulate the secretion of pepsin? The theory has been advanced that histamine does not stimulate the secretion of pepsin but rather produces a large flow of acid which serves to wash out from the tubules pepsin which has accumulated therein. To test the correctness of this theory, Rivers, Osterberg and Vanzant carried out the following experiment which will be reported in more detail elsewhere. In seventy-one persons they injected a dose of histamine to wash out any pepsin which might be in the tubules, and then, before any more of the ferment could accumulate, they gave another injection of the drug. The curve representing median quantity of pepsin in the second period resembled closely that of the first period. When the curves were superimposed, it could be seen that the only place in which they did not almost coincide was in the parts representing secretion in the first ten minutes, and this divergence was due to the fact that the shape of the curve representing median secretion after the first injection of histamine happened to be unusual. The close similarity of the remainders of the two curves indicated strongly that pepsin was formed continuously in answer to the stimulus exerted by histamine. Also in favor of this view was the fact that the quantity of pepsin secreted following the second injection not only was not lessened, as it would have been if there had been only a washing out process, but it was slightly increased. It seems to be proved then that histamine is a powerful stimulant to the cells which secrete pepsin.

The relations between the pepsin contents of the three types of juice.—The character of the regression lines and the size of the coefficients of correlation showed that there is a high degree of positive correlation between the pepsin readings in the three types of juice obtained at different times from one individual. On the average, the figure expressing concentration of pepsin in test-meal juice was 0.63 of that expressing concentration of pepsin in fasting juice, and 0.35 of that expressing the quantity of pepsin secreted in the first thirty minutes after the injection of histamine. Once we had established this relationship, we were able to combine groups of data based on analyses of the three types of juice by reducing them all to terms of pepsin concentration in test-meal juice. This ability to express with one figure all our observations made with different types of juice was particularly helpful when it came to studying pepsin readings in groups of patients with different diseases.

The best type of juice to use.—After we had studied the characteristics of the three different types of juice, the question naturally arose, should we go on using all three types, or is any one of them so much better than the others, that we should use that and discard the others? In attempting to decide this matter we measured the several types of juice by three criteria: (1) variability in measurements of pepsin when repeated tests are made on the same individual; (2) variability in measurements made on a group of patients with a particular disease, and (3) degree of separation between the distributions representing values of pepsin in normal and diseased persons. Other criteria, such as ease of obtaining the specimen, or comfort and convenience of the patient, were not taken into account.

With all types of juice, the range of the measurements was so great that we felt the need for accumulating large groups of data before attempting to draw conclusions in regard to differences between normal and diseased persons or between patients with different diseases.

On estimating the coefficient of variation (the standard deviation expressed as a percentage of the mean) for repeated measurements of pepsin in gastric secretion taken *from one person*, we found that values

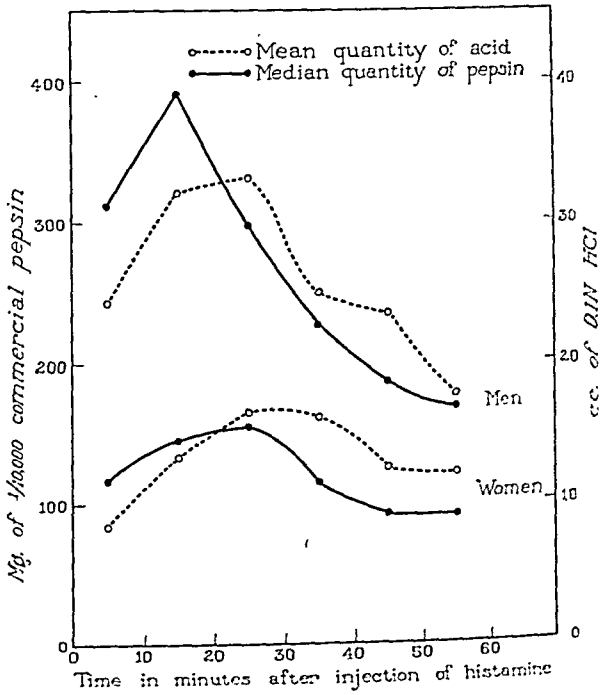

Fig. 3. Curves representing quantities of acid and pepsin secreted in the six specimens of histamine juice. Data were taken from records of normal persons and of persons with gastric and duodenal disease.

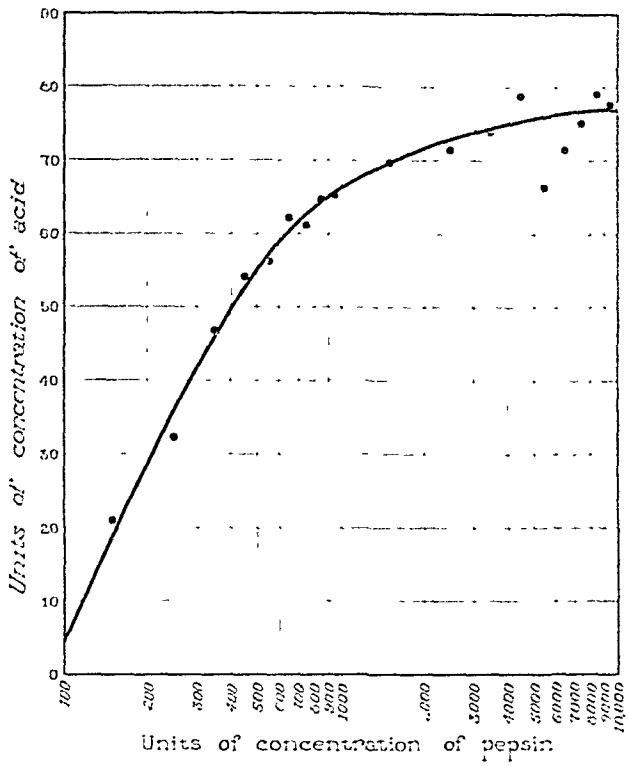

Fig. 4. Regression of mean concentration of acid on concentration of pepsin in 3232 samples of histamine juice obtained from normal men and women, and men and women with diseases of stomach and duodenum. Semilogarithmic paper was used.

from test-meal juice showed the least variability. We obtained from two to nine samples from each of thirty-three persons, and found the coefficient to be 21 per cent. For the corresponding free acid values, it was 13 per cent. The variation in repeated pepsin readings made on fasting and histamine juice was in each case about 50 per cent greater than in readings made on test-meal juice.

The coefficients of variation for pepsin concentrations in samples of test-meal and fasting juice taken *from many normal men and women* were respectively 63 per cent and 108 per cent. For quantity of pepsin secreted in the first thirty minutes after injecting histamine the coefficient was 111 per cent. The coefficient of variation for free hydrochloric acid was one and a half times greater for values in histamine juice than for values in test-meal juice, and it was three times greater for values in fasting juice than for those in test-meal juice.

When it came to distinguishing between normal persons and persons with gastric or duodenal disease, we were unable to find that pepsin determinations on any one juice were better than those on another.

We conclude, then, that test-meal juice is the best to use routinely for clinical determinations of pepsin because it is better than the others when judged by the first two of the three criteria, and so far as the third criterion goes, test-meal juice is as good or bad as are the other two. It is commonly assumed that analyses of histamine juice must be of more clinical value than analyses of test-meal juice because with the former there is no dilution with the fluid in the test-meal; furthermore, one can measure volume of secretion, and can thereby estimate the quantities of acid and pepsin secreted in a given time. Actually, however, when put to a statistical test, analysis of histamine juice did not prove to be as helpful clinically as were analyses made of test-meal juice.

Correlation between concentrations and quantities of acid and pepsin secreted.—Because acid and pepsin must work together to achieve the digestion of protein, and because often they respond to one and the same stimulus, one would expect usually to find them secreted more or less simultaneously and in parallel concentrations, but because they come from different cells, one would expect to find some conditions under which one would be secreted without the other.

Our studies showed that in histamine juice there was usually a considerable degree of positive correlation between concentrations of acid and pepsin, between concentrations of pepsin and volume of juice secreted, and between concentrations of acid and volume of juice. Because of the nonlinear relation between concentrations of pepsin and acid it would not have been pertinent to calculate the coefficient of correlation, and hence we could only draw the regression line as shown in Figure 4. Semilogarithmic paper was used in order to reduce somewhat the curvature of the line and to condense the space required for the scale of pepsin values. Since the points in this figure represent means of the individual observations which, if plotted, would be scattered widely above and below the regression line, it is obviously impossible to use this line to predict with precision the concentration of acid that should go with a given concentration of pepsin. All one can say is that it is probable that a stomach

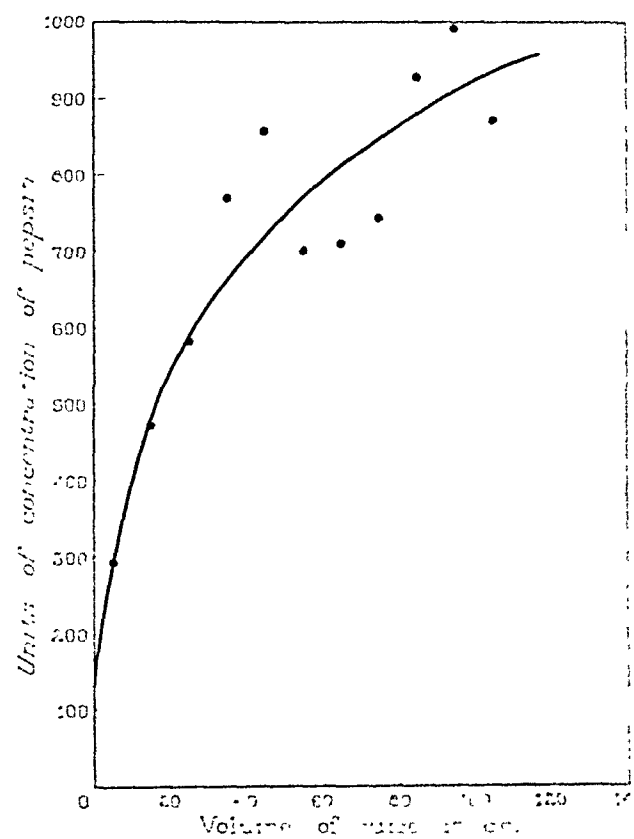

Fig. 5. Regression of median concentration of pepsin on volume of secretion in 3232 ten-minute samples of histamine juice obtained from normal men and women, and men and women with diseases of stomach and duodenum.

which secretes acid in high concentration will also secrete pepsin in high concentration.

When we studied the correlation between concentrations of acid and pepsin in test-meal and fasting juice we obtained the same type of curved regression line observed in the case of histamine juice.

Figure 5 shows that in histamine juice there is a positive correlation between concentration of pepsin and volume of secretion.

Because with histamine juice, the relation between concentration of acid and the amount of secretion was linear in character, we could calculate the coefficients of correlation for each of the six successive samples of juice. They were as follows: for specimen 1, +0.411; for specimen 2, +0.449; for specimen 3, +0.335; for specimen 4, +0.326; for specimen 5, +0.395; for specimen 6, +0.254. These values are lower than some that have been published by other workers.

Since the volumes of test-meal and fasting juices are not dependent on the rate of secretion alone but on a number of other variables, it did not seem worth while to study with such juices the relationships of volume of the gastric contents to concentrations of pepsin and acid.

Striking evidence of the occasional independence of the activities of the parietal and the chief cells was found in the fact that high concentrations of pepsin were observed at times in juice which did not contain any free acid. This apparent independence of the two secretory functions was particularly remarkable when met with during the analysis of histamine juice.

Our reading of the literature led us to believe that we would seldom find much pepsin in juice which did not contain free hydrochloric acid, but actually, we found a number of samples of achlorhydric juice with much more than the normal concentration of pepsin. We cannot say that in these cases the stomach was incapable of secreting hydrochloric acid, but we do know that on a number of occasions when such a stomach was not secreting acid, it secreted pepsin in high concentration. A concentration of pepsin of 3130 units was the maximal one seen in a sample of achlorhydric juice and, strange to say, this specimen was obtained after the injection of histamine, a drug which is supposed to make the parietal cells secrete acid if this is possible. Other values of more than 500 units met with in achlorhydric juice were 530, 535, 540, 580, 680, 790, 980, 1070, 1410, 1450, 1570, 1990, and 3130.

The distribution of figures for concentration of pepsin in achlorhydric juice was skewed just as were the distributions for data from all persons studied. The median was 125 units. In none of the samples of achlorhydric test-meal juice was the concentration of pepsin higher than 300 units. In samples of achlorhydric fasting juice there were 5 per cent with pepsin in concentrations higher than 500 units. With histamine juice there were about 3 per cent of such samples.

We have also seen some samples of juice with a fair concentration of acid and no measurable peptic activity. In two of these cases we had been making daily analyses for two months and hence were able to say that it was an occasional happening which we could not account for in any way (3).

The influence of sex on the secretion of pepsin.—Just as with concentrations of acid secreted, so also with concentrations of pepsin, there is such a marked sexual difference that for statistical purposes, one cannot combine data from men and women. As will have been noticed from the figures presented in this paper, mean and median values for women are usually lower than those for men. Whenever, in the tables, this difference fails to appear, it may be attributed to the fact that we were dealing with a small group of data, some of which were far from the modal value.

The effect of age on the secretion of pepsin.—By combining readings from the three types of juice obtained from persons with duodenal ulcer, we were able to obtain the figures plotted in Figure 6. There it will be seen that the concentration of pepsin falls off with age much as we have found the concentration of acid to do. A similar change in acidity with age seen in normal persons was described in detail in a previous paper (4). It is interesting to note here that Polland (5) has shown that volume of secretion also diminishes with age. The impression gained is that if this loss of power to secrete acid and pepsin, which comes after middle age, is due to a progressive atrophy of the gastric mucosa, then the parietal and chief cells must suffer together.

SUMMARY

A statistical analysis has been made of the concentrations and amounts of pepsin in 6200 samples of gastric juice. Measurements were made with a modification of the Gilman and Cowgill method.

Because of the wide variability in concentrations of pepsin, large groups of data are needed for satisfactory statistical analysis. The median rather than the mean was used as a measure of central tendency because of the marked skewness of the distributions.

Comparative studies were made with test-meal, fasting, and histamine juice.

In test-meal juice, the median for men was 151 units; for women it was 110 units. Five hundred units was taken as the upper limit of normal for both men and women.

In fasting juice, concentrations of pepsin were higher and more variable than in test-meal juice.

In histamine juice the concentrations of pepsin were the highest of all, and the variability was great. In men, the median value ranged in the six samples from 420 to 1160 units; in women it ranged from 285 to 660 units. The curves representing concentration and quantity of pepsin secreted after injecting histamine rose rapidly for twenty minutes and then fell for thirty minutes. The peaks of these curves represent-

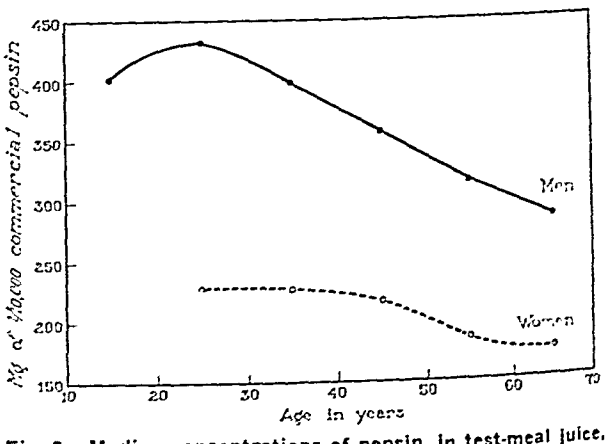

Fig. 6. Median concentrations of pepsin, in test-meal juice, at different ages, in men and women suffering with duodenal ulcer.

ing secretion of pepsin appeared ten minutes earlier than did the peak of the curve representing secretion of acid.

The theory that histamine does not stimulate secretion of pepsin but simply washes it out of the tubules was disproved by comparing curves representing secretion of pepsin in two histamine tests run one immediately following the other.

In studying pepsin in persons with gastric and duodenal disease, test-meal juice was found to be preferable to fasting or histamine juice because in the first named juice the concentration of the ferment was less variable, not only in the individual but in the group.

Because a fairly constant numerical relation was found between figures expressing secretion of pepsin in the three types of juice, it is now possible and often advantageous to convert values obtained with fasting and histamine juice into terms of values for test-meal juice.

There is a considerable degree of positive but nonlinear correlation between the concentrations of acid and pepsin. However, on several occasions, large concentrations of pepsin were found in achlorhydric juice. Occasionally, also, pepsin could not be found in a sample of juice which contained free acid.

There was some degree of positive nonlinear correlation between concentration of pepsin and volume of juice secreted.

The secretion of pepsin was found to decrease with age, much as secretion of acid does. Concentrations of pepsin and amounts of pepsin secreted were decidedly greater in men than in women.

Permeability to Egg Albumin in Peptic Ulcer*

A Possible Test for Activity of Peptic Ulcers

Preliminary Report

By

MEYER B. MARKS, M.D.
CHICAGO, ILLINOIS

THE permeability of the gastro-intestinal tract to foreign protein has always been a matter of interesting conjecture. Schloss and Worthen (1) found that when nutritional disorders occurred in children, the digestive tract favored the absorption of foreign protein. Modigliani and Benini (2) observed that casein may be detected in the urine of infants affected with gastro-intestinal disorders by means of anti-casein serum from rabbits. Lust (3) and many others have demonstrated that nutritional disorders in children may permit the passage of undigested protein through the gastro-intestinal tract.

Accordingly, it was decided several years ago to study the permeability of the gastro-intestinal tract of adults to foreign protein. It was observed that when an ulcer existed in the gastric or duodenal mucosa, raw egg white passed through the defect in an unaltered state. A series of eighty-nine patients selected from the wards of the Cook County and Research and Educational Hospitals were fed raw egg white and their urine examined for undigested protein by means of the precipitin test. It was found that in normal individuals and in patients without gastro-intestinal lesions, no precipitin reactions for egg white were present in the blood or in the urine. In individuals with pathology in the gastro-intestinal tract, particularly about the region of the stomach and the duodenum, positive precipitin tests in both blood and urine were demonstrated. In another group of patients, whose lesions were lower down in the bowel, possibly along the terminal ileum or colon, in most cases no permeability to raw egg white was apparent.

A number of patients with active and healed peptic ulcers of the stomach and duodenum were then tested. In this particular series it was shown, with a few exceptions, that the foreign protein was present in the urine and blood of individuals with active peptic ulcers. However, in the majority of cases with healed peptic ulcers no undigested protein passed through the gastro-intestinal tract.

TYPES OF ULCER PATIENTS TESTED

The patients tested in this group may be classified into:

(1) active ulcer group
(2) healed ulcer group

1. The active ulcer group included the three following types:

(a) Individuals presenting subjective symptoms of ulcer with clinical as well as roentgenologic evidence

*From the Departments of Physiological Chemistry and Medicine, University of Illinois College of Medicine and the Cook County Hospital, Chicago.
*Read in part before the Central Interurban Clinical Club, May 4, 1935, and at the meeting of the American College of Physicians, April, 1934, Chicago; and before the Central Society for Clinical Research, Nov. 2, 1935, Chicago.
*This paper was awarded the Beaumont Prize, for 1935, at the College of Medicine, University of Illinois, an Annual Grant from the Beaumont Memorial Fund, donated by Frank Smithies, M.D., Chicago, in 1927.

(b) Individuals presenting an atypical symptomatology with positive roentgenologic evidence of peptic ulcer.

(c) Patients with long-standing quiescent ulcers with exacerbations of acute symptoms.

2. The healed ulcer group comprised three types:

(a) Perforated peptic ulcers which had been sutured at operation.

(b) Perforated peptic ulcers which had been sealed over with exudate and omentum without operation.

(c) Medically healed ulcers in individuals who are now neither taking powders nor being restricted to a special diet, but who at one time showed positive clinical and roentgenologic evidence of an active ulcer.

TECHNIC OF THE TEST

Rabbits were injected intramuscularly with about 30 c.c. of a 1:10 dilution of egg white fixed in aluminum cream according to the method of Hektoen and Welker (4). At the end of fourteen days, the serum was tested for its precipitin titre for egg white. If the antiserum exhibited a titre of 1:100,000 or more, the animal was bled to death and the serum preserved in tightly corked vials, into which a few drops of redistilled chloroform were placed to prevent mold formation. If the titre of 1:100,000 was not reached, the rabbits were allowed to live for another ten to fourteen days and were again tested. Occasionally, further injections of egg white were given until a serum of sufficient strength was obtained. No serum was used unless it had a titre of 1:100,000 or more.

The whites of two raw eggs, stirred into a little water, were then fed to individuals, with and without digestive tract pathology. The egg white was given at 11 a. m., about three hours after breakfast, and the patients instructed not to eat anything until 1 p. m. Individual voidings of urine on the first day were taken at 12 noon, 3 p. m., 6 p. m., and 9 p. m. Twenty-four hour specimens from 7 a. m. to 7 a. m. were taken on the second day and likewise on the third day. In the last group of about fifty patients, the raw egg white was fed at 11 a. m.; and only one twenty-four hour specimen from 11 a. m. to 11 a. m. was collected.

A higher titre of antiserum can be obtained by using crystallized egg albumin as the antigen instead of raw egg white. The titre obtained in the antisera prepared with crystallized egg albumin ranged between 1:500,000 and 1:1,000,000. It was this antiserum which was used in the last fifty cases. The method of preparation of the anti-egg albumin serum was exactly the same as in the case of the egg white serum. The crystallized egg albumin was prepared according to the method of Cole (5).

In the first forty patients, the urine was tested undiluted and in dilutions of 1:10, 1:100, and 1:1000 with normal saline. In the last fifty cases, the urine was tested either undiluted, or diluted 1:10 with normal saline. Occasionally, where the precipitating serum and the undiluted urine mixed without layer formation, the urine was diluted 1:2 and tested. One-half c.c. of the antiserum was added to each precipitin tube containing one-half c.c. of the undiluted and diluted urine, so that distinct layer formation occurred. The tubes were left undisturbed at room temperature for one hour and the results noted. Control tests were carried out with one-half c.c. of normal rabbit serum in place of the precipitating serum, and also with the addition of one-half c.c. of the antiserum to the normal saline.

A positive test was one that showed a definite white band at the junction of the urine and serum layers. A *questionable result* was one that showed no white band formation, but a white precipitate in the upper portion of the urine in the precipitin tube.

In order to prove that the undigested protein was present in the blood stream, in the first six patients with active ulcers, blood samples were drawn on the first day at 2 and 4 p. m. (along with urine voidings at 12 noon, 3, 6, and 9 p. m.). In both blood and urine, the precipitin reaction was positive for egg albumin. It had been observed by Schloss and Worthen (1), Ascoli (7), Lust (3), and others that the foreign protein appears in the blood stream earlier and for a shorter period of time; while in the urine it appears later but persists longer. The testing of blood for the undigested protein was then abandoned, as this would have necessitated frequent withdrawals of blood specimens, a matter of great inconvenience to most patients.

DISCUSSION OF RESULTS

In Table I may be seen a series of twenty-nine cases without peptic ulcer pathology. Twenty-two of these gave a negative precipitin reaction. Two gave a doubtful result and five were definitely positive. The five patients whose urine showed a positive reaction were diagnosed tentatively as having dietary diarrhea (2 cases), spastic colitis, drastic catharsis, and tapeworm infestation. The two cases of dietary diarrhea and those of spastic colitis and tape worm infestation all gave a positive chemical test for blood in the stools (four plus in the cases of spastic colitis and tape worm infestation). No roentgenographic studies of the gastro-intestinal tract had been made at the time of the testing of the five patients. The positive precipitin reaction in the case of the patient who had been given drastic cathartics (A.S.) cannot be explained unless some overlooked gastro-intestinal pathology was present. In the four other positive patients, it is fairly certain that a defect of the mucosa of the digestive tract exists, the site of which cannot be definitely located.

The two cases which gave a doubtful reaction were those of a patient with a bleeding carcinoma of the esophagus and one who had ulcerative colitis. The latter patient was given a two quart tap water enema into which had been stirred the whites of two raw eggs. The enema was expelled almost as soon as given. (Two days before this patient had received the egg white by mouth. No absorption of the foreign protein was observed).

Four cases of liver and gall bladder disease showed no permeability of the gastro-intestinal tract to foreign protein. The test may prove to be of some value in facilitating a possible differentiation between gall bladder and gastric disease.

In one case, that of carcinoma of the stomach, the patient (T.H.) had been previously diagnosed as having a gastric ulcer. On testing him with egg white a negative precipitin reaction was obtained. When the patient was operated upon, one week later, he was found to have an ulcerative, indurated carcinomatous lesion of the pars media.

DISCUSSION OF RESULTS

Table II refers to a group of forty-two patients having active peptic ulcers. All except thirteen showed evidence of the absorption of foreign protein. Six of the patients (those marked with an asterisk on the Table) had completed a course of treatment with intramuscular injections of an aqueous solution of histidine.

In all the cases of bleeding peptic ulcer, the precipitin reaction was striking. It seems in these cases that when the chemical test for blood on the feces is strongly positive, the precipitin reaction on the urine also is strikingly positive, as manifested by a heavier white band at the junction of the urine and antiserum. A fair conception then of the size and extent of the pathologic process may be had from the amount of precipitate which forms between the urine and the antiserum.

One patient (C.L.) who now is positive also showed a positive precipitin reaction one year ago.

Another case (A.B.), who gave a positive result at one time, became negative six months later after being placed upon proper dietary regime.

Of the three patients who gave "doubtful" evidence of permeability to foreign protein, one (A.W.) had received a course of histidine injections. Another patient (V.M.) showed positive roentgenologic evidence of a small penetrating ulcer on the lesser curvature of the pars media. On three occasions her stools have given a negative chemical test for blood. There is no explanation for the "doubtful" result in the third case (R.J.).

Two of the ten patients (H.W. and H.B.), who gave negative precipitin reactions, should really have been placed into the healed ulcer group. One (H.W.) came to operation where it was found he had a mass of dense adhesions binding down the stomach and duodenum to

the surrounding structures, the result, the surgeon thought, of an old healed "forme fruste" ulcer. The other patient who gave a negative result (H.B.) has been a ward worker in the hospital for the past three years and may have become healed in the course of his stay.

The results of the remaining eight ulcer patients who showed no undigested protein in the urine cannot be explained unless the test was at fault or the roentgenologic evidence insufficient. In the majority of the patients in this group the history and clinical findings were atypical. Stool examinations for blood were negative in most of these cases.

DISCUSSION OF RESULTS

The last series of cases deals with a group of eighteen healed peptic ulcers (Table III). The three gastro-enterostomized patients in this group gave a negative precipitin test. Of the eight perforated duodenal ulcer cases, seven were operated upon and one healed on Ochsner's therapy without operative interference. Six of these showed no precipitin reactions for egg white in the urine. The two patients, whose gastro-intestinal tracts were permeable to undigested protein, both complained of slight pain after eating at the time their urine was tested. The two patients on dietary management, who showed positive precipitin reactions in the urine, have both complained of symptoms within the last month.

COMMENT

It may be possible to show the presence of a healthy or pathological gastro-duodenal mucosa by the simple test of feeding raw egg white to patients and testing for egg white protein in their urine by means of the precipitin test. It would appear that this test can be utilized to determine whether a peptic ulcer is active or quiescent. The test may possibly be of use in differentiating between gall bladder and gastric disease. It is not believed that the test is specific for duodenal or gastric ulcer alone, but that other ulcerative conditions of the gastro-intestinal tract may give a positive precipitin reaction.

Further investigations will soon be carried out on more cases of gall bladder and peptic ulcer disease. Ulcerative conditions of the lower bowel will be studied, not only by means of oral ingestion of raw egg white, but also by means of retention egg white enemas. (A possible explanation of the failure to demonstrate precipitin reactions in cases of ulcerative lesions of the colon and terminal ileum is that the protein fed by mouth becomes broken down by digestion and bacterial decomposition long before the ulcerative defects of the mucosa are reached).

Considering the circumstances under which this work had to be carried on, there is a possibility that some of the false positive precipitin reactions may have been true reactions and that the diagnosis was erroneous. Some of the false negative reactions may be attributed to partial healing of the ulcer.

CONCLUSIONS

1. It seems that individuals without gross lesions in the mucosa of the upper portions of the alimentary tract do not give the egg white precipitin test in the urine, excepting in 20% of cases that might possibly be considered as having given a false positive result.
2. Patients with active peptic ulcers whether located in the stomach or duodenum have yielded the precipitin reaction in 75% of the cases. This might be considered to introduce a possibility of a 25% false negative reaction.
3. Patients with healed peptic ulcer gave a negative reaction in all but 20% of the cases studied.
4. In spite of the possibility of false positive and false negative reactions in a certain percentage of cases, it seems that the test may be of value as corroborative evidence of the probable presence, or absence, of active peptic ulcer, or other mucous membrane lesions, in the upper portion of the digestive tube, and in differentiation from gall bladder and other diseases producing similar clinical pictures.

I wish to thank Dr. William H. Welker for his kind help in directing this problem. I also wish to thank Dr. Harry A. Singer and his associates for the clinical case material they have furnished.

SECTION III—*Nutrition*

The Influence of Fruit Ingestion Before Meals Upon the Bacterial Flora of Stomach and Large Intestine and on Food Allergins*

By

OLAF BERGEIM, M.D.
ARTHUR HANSZEN, M.D.
and
LLOYD ARNOLD, M.D.
CHICAGO, ILLINOIS

THE influence of various fruits upon gastro-intestinal function has been studied in this laboratory for the past few years. The intra-alimentary contents, from the oral cavity to the anal opening, depend upon the materials ingested, the fluids secreted, and the bacterial flora in the lumen of this tract. We have been particularly interested in the bacterial flora and the acid-base equilibrium of the contents of the gastro-intestinal tract. There are definite communities of bacterial life residing within the lumen of the alimentary canal. The flora of the various zones or levels are distinct and characteristic, although the lumen and mucosa are continuous.

Arnold, Ryan and Korando (1), Arnold (2) reported studies on fruit and vegetable feedings in rodents in relation to bacterial flora, acid-base equilibrium and susceptibility to orally ingested pathogenic bacteria. It was decided to extend these observations to include some human subjects. In the course of this work certain fruits were fed to fasting persons and the gastric response to such a fruit meal followed by the usual methods of aspirating samples at short time intervals. The bactericidal power of the gastric contents was determined during the course of these studies. Hanszen (3) reported these observations in a preliminary paper.

During the course of the above mentioned experiments we became interested in the problem of ingesting a small amount of some fruit an hour or so before a regular meal. We began these studies in this manner because we wished to determine the gastric pattern of reaction to the fruit alone. It was necessary to study the influence of a fruit premeal on the utilization of food ingested at the subsequent meal before such a dietetic procedure could be recommended. We wished to study in greater detail the passage of viable bacteria from the stomach to the large intestine. The factors influencing the length of sojourn of orally ingested bacteria in the large intestine was another part of our problem.

*Departments of Physiological Chemistry, Bacteriology, and Public Health of the University of Illinois College of Medicine and Research Laboratories of the State Department of Public Health, Chicago.
Submitted Dec. 17, 1935.

THE INFLUENCE OF A PREMEAL ON THE PASSAGE OF ORALLY INGESTED BACTERIA TO THE LARGE INTESTINE

Five subjects were used for the first part of these experiments. There were seventy-five test meals carried out with high enemas for recovery of ingested bacteria. A Rehfus tube was used for aspirating gastric contents. All subjects were young adults with normal gastric patterns. The gastric contents after each premeal, and just before the ingestion of the test meal containing B. prodigiosus was aspirated. The hydrogen-ion concentration was more acid than pH. 3.0 in each instance; that is, each subject had free acid at the time the subsequent meal was ingested. Only one protocol will be given as an example of this experiment. Table I shows the results of fourteen experiments carried out on a young male age twenty-seven. The type of premeal, the subsequent bacterial test meal, the time elapsing between the two and the total number of viable B. prodigiosus ingested, the total number recovered in a viable state from the colon washings with the per cent recovered are indicated in this table.

The next series of experiments were to test the influence of bananas, oranges and apples when eaten one hour before a meal, upon the passage of living bacteria through the stomach to the large intestine. The fruit was ingested after twelve hours' fasting, and one hour later 200 c.c. of fresh whole pasteurized milk containing a known number of B. prodigiosus. Several hundred very small colored paraffin beads were added to serve as markers for subsequent colon washings. These wax beads float on top of the aqueous suspensions of fecal material. Different colored paraffin beads allow excellent segmentation of large intestinal contents in relation to time of food ingestion. No food or water was consumed before the next regular meal, which was four hours after the B. prodigiosus and milk was ingested. Different colored paraffin beads were used as markers for this meal. Eight hours after

TABLE I

Influence of premeal upon passage of viable bacteria to large intestine

Pre Meal	Test Meal	Interval between meals	B. prodigiosus in million		Percent B. prodigiosus recovered

W. B.		1108.00	5.375%
F. B.		1108.00	9.505%

the results obtained using fresh banana, orange and apple. The number of viable B. prodigiosus ingested with the milk and the percentage recovered from the enema fluid are indicated. The first results shown in this table are controls with 200 c.c. plain milk plus the test dose of B. prodigiosus without a fruit premeal to show the passage of these bacteria through the stomach and small intestine down to the lower levels of the large intestine in a viable state.

Dessicated banana and oranges were used for premeals in the same way, using the same technic as for the fresh fruit. These dried fruit samples were in the form of flasks or films, supplied by the courtesy of the Sardik Laboratories, New York City. Table III gives the results of these experiments.

SUMMARY

The gastro-duodenal bactericidal mechanism is most effective in preventing viable bacteria reaching the large intestine when the gastric contents contain free acid, or when the material within the lumen is completely saturated with acid. A small premeal aids in creating this type of intra-gastric environment.

Many of the test bacteria administered with fresh whole cow's milk (200 c.c.) can be recovered in a viable state from the large intestine eight hours after ingestion. One banana eaten one hour before the milk is ingested reduces the number of viable test bacteria recovered to less than one-half of one per cent. We found banana more effective as a premeal than orange and apple in this respect. Dried apple and banana in the same quantities exercised similar influences in the destruction of orally ingested bacteria under the conditions of our experiments.

TABLE III

The influnce of dessicated apple and banana on passage of test bacteria through the alimentary tract. Subjects fasted twelve hours before fruit premeal. Two hundred c.c. of whole milk inoculated with B. prodigiosus were ingested one hour later

Subject	Premeal	Millions of B. prodigiosus ingested	Percent of B. prodigiosus recovered from the colon after 8 hrs.

THE INFLUENCE OF FRUIT PREMEAL UPON THE UTILIZATION OF PROTEINS, FATS AND CARBOHYDRATES OF THE SUBSEQUENT MEAL

Pincussen (4) reviewed the literature on the utilization of various food by man. It was necessary to establish the comparative utilization of the proteins, fats and carbohydrates in a meal including a given amount of fruit, then for the same meal with the fruit eaten one hour before. The authors visualize an increasing field of usefulness of the premeal for certain types of gastric functions and for added protection of the alimentary tract against exogenous ingested bacteria. The possibilities of utilizing the premeal for food sensitive individuals will be discussed later in this paper. It was therefore necessary to establish the food utilization of the regular meal after a fruit premeal. The utilization of fats, carbohydrates and proteins introduced into an actively secreting and digesting stomach has not been recorded in literature.

Utilization of proteins: Nine healthy subjects of ages seventeen to fifty-eight years were used in these experiments which involved ninety-two analyses. Three different protein test meals were used. The program of each subject was as follows:

First day:

7-8 A. M. A high enema consisting of two washings of 1500 c.c. each.

9 A. M. Test meal followed immediately by ingestion of two bananas.

1 P. M. Four bananas.

6 P. M. A high enema, two washings of 1500 c.c. each.

Second day: Same as the first day.

Third day:

7-8 A. M. Enema.

9 A. M. Two bananas.

10 A. M. Test meal.

2 P. M. Four bananas.

7 P. M. Enema as on first day.

Fourth day: Same as on third day.

The total quantity of the evening washings was made slightly acid by addition of sulfuric acid to prevent loss of ammonia. One hundred grams of corn starch were then added and the mixture was heated to boiling while being stirred. This yielded a rather thick homogeneous fluid suspension of the particulate matter obtained from the large intestine. Two 100 c.c. samples of the liquid were then analyzed for nitrogen by Kjeldahl's method, and the total nitrogen recovered from the colon nine hours after the test meal had its origin in the bananas ingested and in mucus and bacteria from the intestine as well as in the test meal. However, since these factors were constant throughout all experiments the results are significant since they indicate the relative utilization of the test meal when taken after or with bananas. It is evident from Table IV that protein utilization is practically the same whether the protein is taken on an empty stomach or in one in a state of active digestion.

Utilization of Fat: The program of each subject was the same as that described under Utilization of Protein with the exception that a meal rich in fat was substituted for the protein test meal.

TABLE IV

Protein Utilization: Quantity of nitrogenous material recovered from Colon nine hours after ingestion of the several meals listed below. Each figure represents an average taken from two experiments made on two consecutive days and is the total quantity in grams of nitrogen recovered from the colon

Subject	400 c.c. evaporated milk. Total nitrogen 4.1444 gms.		400 c.c. whole milk. Total nitrogen 2.128 gms.		200 grams lean beef. Total nitrogen 6.132 gms.	
	2 bananas 1 hour before meal	2 bananas with meal	2 bananas hour before meal	2 bananas with meal	2 bananas hour before meal	2 bananas with meal
1	0.560 gms.	0.786 gms.	0.595 gms.	0.480 gms.	0.520 gms.	0.590 gms.
2	0.726 gms.	0.498 gms.	0.520 gms.	0.640 gms.	0.750 gms.	0.845 gms.
3	0.585 gms.	0.690 gms.	0.574 gms.	0.515 gms.		0.625 gms.
4	0.427 gms.	0.535 gms.	0.394 gms.	0.558 gms.	0.726 gms.	0.690 gms.
5	0.640 gms.	0.770 gms.		0.550 gms.	0.824 gms.	0.855 gms.
6	0.432 gms.	0.620 gms.	0.570 gms.	0.728 gms.	0.435 gms.	0.685 gms.
7	0.550 gms.	0.495 gms.				
8					0.843 gms.	0.755 gms.
9					0.740 gms.	0.856 gms.
Average	0.560 gms.	0.627 gms.	0.530 gms.	0.573 gms.	0.691 gms.	0.737 gms.

Colon washings were acidified with HCl to convert fatty salts to fatty acids, and the latter together with neutral fats were extracted by ether. The ether and volatile fatty acids were then driven off by heating in an evaporating dish, leaving only solid fat which was weighed. The volatile fatty acids were eliminated because their origin was most probably in carbohydrate fermentation rather than in the test meal.

Table V shows clearly that fat is utilized as completely when taken into an active stomach as when taken into an empty one.

TABLE V

Fat Utilization: Quantity of fat recovered from colon nine hours after ingestion of a meal consisting of one hundred grams of butter, four slices of bread, two ounces of molasses, two hundred c.c. of skimmed milk. Each figure represents an average taken from two experiments made on two consecutive days

Subject	Fat recovered where two bananas were eaten one hour before the fat meal	Fat recovered where two bananas were eaten just after the fat meal
1	2.854 gms.	3.284 gms.
2	3.047 gms.	3.973 gms.
3	2.902 gms.	2.149 gms.
4	3.105 gms.	3.388 gms.
5	2.324 gms.	2.004 gms.
6	4.107 gms.	3.206 gms.
7	3.528 gms.	3.349 gms.
8	2.947 gms.	3.562 gms.
9	4.055 gms.	3.345 gms.
Average	3.207 gms.	3.140 gms.

Utilization of Carbohydrate: The subject followed the program described under Protein Utilization, this time substituting a meal rich in carbohydrate for the protein test meal, and eliminating the afternoon meal of bananas to avoid introducing any more banana starch into the experiment than necessary. The two bananas eaten in the morning were thoroughly ripe, thus containing little or no starch and being readily digestible.

Table VI gives the analytical method used and the results for this experiment. Evidently a banana pre-meal does not interfere with the carbohydrate utilization of the subsequent meal.

TABLE VI

Carbohydrate Utilization: Quantity of carbohydrate recovered from colon nine hours after ingestion of a meal consisting of 120 grams wheat crackers, two hundred c.c. milk and twenty grams of sugar. Colon washings hydrolyzed at 100° C. for two hours with 2% HCl and analyzed for reducing sugar by Benedict's method. Each figure represents an average taken from two experiments made on two consecutive days

Subject	Grams of sugar recovered from colon	
	Two bananas eaten before the test meal (one hour)	Two bananas eaten with the test meal
1	4.325 gms.	4.505 gms.
2	1.400 gms.	2.740 gms.
3	3.720 gms.	1.848 gms.
4	3.865 gms.	4.007 gms.
5	2.743 gms.	2.526 gms.
6	3.430 gms.	2.460 gms.
7	3.000 gms.	3.050 gms.
8	3.708 gms.	
Average	3.274 gms.	3.017 gms.

SUMMARY

The utilization of proteins, fats and carbohydrates was the same when bananas were ingested before the meal as when this fruit was eaten along with the meal.

FACTORS INFLUENCING BACTERIAL FLORA WITHIN THE LARGE INTESTINE

Since the report upon the destruction of yeast within the large intestine (Montgomery, Boor, Arnold and Bergeim (5)), Bergeim has been studying some of the factors contributing to the toxicity of the intra-intestinal contents. A detailed report of these findings will be published elsewhere. The authors wish here to show the influence of certain fruits upon the bacterial flora of the large intestine.

Bergeim has shown that one of the most toxic substances for yeast and B. coli found in the large intestine is butyric acid. Hydrogen sulphide ranked next in importance as a bactericidal agent for certain bacteria. We have used the contents of the large intestine obtained by enema, using 3000 c.c. of washing fluid, divided into two equal portions. The solid and fluid portions of the suspended fecal material were analyzed separately for hydrogen sulphide and butyric acid content. Direct smears stained by Gram's method were made from the mixed washings.

Three subjects were maintained for four days on the following diet:

Breakfast: Three fried eggs, four strips bacon, two pieces of toast with butter, juice of ½ lemon in a glass of water sweetened with cane sugar.

Luncheon: ½ pound of ground beef fried, four slices of bread, butter, honey, tea.

Supper: ½ pound ground beef fried, gravy, potatoes, bread, butter, honey, lemon juice.

During the four days the urine was tested for indican twice daily by shaking with chloroform and Obermeyer's reagent. Bowel movements were recorded. On the afternoon of the fourth day a high enema was given, two successive washings each with 1500 c.c. of sterile water. The washings were then analyzed quantitatively for butyric acid and hydrogen sulphide. B. coli counts were also carried out on the same individual. This program was then repeated, all conditions being the same with the exception that two bananas were eaten an hour before each regular meal and two more before retiring (eight bananas per subject each day), and the carbohydrate content of the regular meal was reduced in proportion.

Hydrogen sulphide was determined by blowing over the gas with a current of hydrogen into alkaline lead acetate-gelatine solution and comparing colors obtained with those obtained with standard hydrogen sulphide solutions (6). Butyric acid was determined by extracting 200 c.c. portions of the washings (previously acidified with sulphuric acid) three times with 1000 c.c. portions of ether, distilling off the ether, adding 50 c.c. of water and distilling off the volatile fatty acids which were then determined by the isopropyl ether partition method of Osburn and Werkman (7). These methods will be discussed further in another connection.

Table VII gives the results of this experiment. It will be noted that there was a marked reduction in the indican in the urine, decrease in the hydrogen sulphide in the colon washings, and an increase in the butyric acid content of the large intestinal contents after banana ingestion. Correlated with the increased butyric acid content was a relative decrease in the viable B. coli in the washings. The gram positive to gram negative ratio of direct smears from the washings showed a preponderance of gram positive forms following the banana diet. Considerable work has been done in this laboratory in conjunction with the Department of Pediatrics on the bacterial flora of feces of infants fed various carbohydrates. We were unable to show banana powder influenced in any way the gram positive to gram negative ratio. This will be reported in the near future. The observations included in Table VII were washings from the large intestine and hence the bacterial flora may differ from that found in formed feces.

The results reported in this experiment substantiate Bergeim's work. He has shown that *in vitro* as well as *in vivo* experiments the concentration of butyric acid in the large intestine was perhaps the most important single factor in reducing the number of viable bacteria.

SUMMARY

On the high banana diet, amounts as high as 578 c.c. of 0.1 N butyric acid were found in the colon and the average amount was 329 c.c. The amounts found in the upper colon averaged 194 c.c. of 0.1 N butyric acid. Following the enemas of 3000 c.c. of water, the average recovery of material was 3100 c.c. The bulk of material as it existed in the colon and hence the concentration of butyric acid in the colon cannot be accurately estimated from these findings. However, the

average amount of material in the intestines can hardly have been much over 300 c.c. on the average, and the concentration of butyric acid not much less than 0.1 N. The pH values of the contents of the upper colon were between 6.0 and 6.5. In *in vitro* experiments it has been shown that concentrations of 0.05 N of butyric acid at pH 6 reduced the growth of B. coli to about 1/100th of that in the control, and that at pH 6.5 a reduction of growth to 14% of normal was obtained with 0.1 N butyric acid. The decreased number of B. coli in the intestines on the banana diet might therefore be accounted for by a limitation of growth by the butyric acid present, assisted by acetic acid also present, though these need not be the only factors concerned.

On the banana-free diet, on the other hand, the butyric acid concentrations were much lower, and the pH so near neutrality that no inhibiting effect of butyric acid on B. coli would be expected. This agrees with the high counts of B. coli found on these diets.

It appears therefore that the reduction in the numbers of B. coli on the high fruit diet was at least in part due to the increased production of butyric acid on this diet, associated with the lowered pH.

HABITUAL FRUIT PREMEAL

The use of the fruit premeal was started in order to test gastric response to the fruit alone, free of any other form of food. There were certain advantages, both in gastric and intestinal bactericidal function, shown to follow the ingestion of a small amount of fruit one hour before the regular meal. It has been shown also that this does not interfere with the utilization of fats, carbohydrates and proteins of the subsequent meal. It was thought necessary to test the general reaction of a group of normal adults to the habitual use of a fruit premeal.

Ten subjects have been on a banana premeal for fourteen weeks. Two bananas were eaten one and one-half hours before lunch, before dinner, and just before retiring at night. A daily report was made on bowel movements, gastric and intestinal disturbances, gas, discomfort, fatigue, both mental and physical and appetite. Weight was recorded twice weekly. No ill effects were noted by any subject. Three of these ten subjects had been constipated. After six to eight days on the banana premeal, bowel movements occurred daily, with large soft stools. Four of the ten subjects recorded noticeable gas in the large intestine the first three days on the premeal diet, but none after this time. The appetite was not affected. There may have been less mental and physical fatigue, particularly before lunch and dinner time. Our object was to see if any abnormal reactions would be noticed by people on a fruit premeal for several months. No disadvantages were found. Three months after this experiment was stopped, six of the eight adults are continuing the banana premeal habit; the reasons they give are regular bowel movements, and lessened mental and physical fatigue.

INFLUENCE OF FRUIT PREMEAL ON FOOD ALLERGINS

The authors realize that allergy to foods is a very big subject and is now receiving considerable attention. It is not our purpose to deal with the disputed mechanism of this reaction, but we wish to record some observations we have made using the fruit premeal to produce an actively digesting gastric environment at the time the specific sensitizing substance was ingested. It seemed logical to assume that if the anti-

TABLE IX

genic protein causing the food sensitivity was hydrolysed rapidly in a gastric lumen containing free acid and pepsin, then the phenomenon of hypersensitivity to the specific protein substance might be reduced or it may be possible that the reaction would not occur. We wish to report our experiences and observations as far as we have carried them.

The destruction of the sensitizing antigen in foods by gastric digestion would depend upon the presence of pepsin. We therefore determined the relative peptic digestion of aspirated gastric contents after the ingestion of fruits. Table IX gives the results using four healthy subjects.

One banana was ingested by a fasting, young, normal adult. The gastric contents were aspirated after one and one-half hours. This material (pH. 2.0) was used to digest rag-weed pollen protein, one hour incubation at 40° C. The tests were set up as follows: 0.2 c.c. pollen extract plus 0.8 c.c. gastric banana contents; incubated one hour at 40° C., then brought to a pH of 7.1 by addition of sodium carbonate. This digest was then used as antigen for skin tests on known sensitive patients. The first two columns in Table X give the results of two separate experiments, run with different pollen extracts and gastric juice from two different normal subjects. The third column in Table X consists of the following: 0.8 c.c. gastric contents after banana ingestion (pH 2.0) brought to pH 7.1 with sodium carbonate. The fourth column in Table X are the results using the following antigen: 2.0 c.c. pollen extract plus 0.8 c.c. 1/10 N. hydrochloric acid and incubated one hour at 40° C., then brought to pH 7.1 with sodium carbonate. The fifth column are the results from the following antigen: 0.2 c.c. pollen extract plus 0.8 c.c. disodium phosphate incubated one hour at 40° C., reaction adjusted to pH 7.1. The last column represents the skin reactions after boiling the pollen extract and adjusting to pH 7.1 with sodium carbonate.

There were several ways of approaching this problem. We began by digesting the specific food with gastric juice as outlined in the experiments using ragweed pollen. We thought these results might not be conclusive, so we next resorted to the use of the human stomach. It is well known that the allergic reaction following ingestion of a given specific food substance is variable, at times it may be absent, this is probably rare, but there are many degrees in the intensity of the hypersensitive reaction. We realized we did not have sufficient time at our disposal to do enough actual feeding experiments on food allergic cases to obtain the most desirable information. We therefore decided to use the skin testing technic and digest the antigenic material in the gastric lumen of normal subjects. The specific food substance to be investigated was ingested into a fasting stomach and aspirated fifteen minutes afterwards. The other series of antigens were prepared by ingesting one banana and, after one hour, eating the same amount of the same specific food and aspirating after fifteen minutes. Two antigens were used for skin tests on susceptible patients. One had fifteen minutes contact with an empty stomach, the other after fifteen minutes contact with an active digesting stomach. The gastric aspirations from the fasting stomach were diluted three times with buffered phosphate solution and adjusted to pH 7.1 with solid carbonate. The gastric aspirations from the premeal digesting stomach was diluted the same, and the reaction was adjusted to pH 7.1 with solid sodium carbonate. The physical consistency and intensity of reaction caused us to use this method of procedure.

The specific foods tested were blue-berries, peas, milk, beans, radishes, walnuts, hazel nuts, strawberries, beef and rye bread. The Allergy Clinic of this institution cooperated with us in placing patients sensitive to these food substances at our disposal for study. Table XI gives the results of our observations. The short time interval of 15 minutes was chosen as our preliminary test. It has been necessary to discontinue our work, and longer digestive periods have not been carried out as was originally planned.

SUMMARY

A fruit premeal offers a method of reducing the irritating properties of food allergins. Our results can only be offered as preliminary studies, but are encouraging enough to warrant further observations.

DISCUSSION

We became interested in the premeal, or between meal, fruit feeding because of certain observations

TABLE X

made during fasting periods of the day to determine the gastric pattern of reaction which would follow the ingestion of fruit alone. We observed a prompt response on the part of the stomach to ingested fruits. The banana causes a rapid concentration of acid and pepsin after ingestion. The banana is buffered very well, and requires a relative large amount of acid to completely acidify. The progressive accumulation of

TABLE XI

The influence of a fruit premeal upon the antigenicity of food allergins. The specific allergic food (column 2) was ingested by a normal subject. One sample was ingested after arising in the morning (column 3), one sample was eaten one hour after one banana was ingested (last column). Fifteen minutes after ingesting the specific food the gastric content was aspirated and each sample used as antigen for skin testing of known allergic patients (column 1)

acid after ingestion of fresh bananas has a "protein-like" gastric pattern, similar to the free and combined acid figures one encounters so frequently after a protein test meal. We became interested in the between meal feeding of fruits from a bacteriological and public health standpoint. We were primarily interested in the passage of orally ingested bacteria through the gastric barrier, and reaching the large intestine in a viable state. This led us to study in greater detail the relationship between gastric acidity and viable bacterial flora within the lumen of this organ.

The influence of a fruit premeal on the ability of the stomach to destroy ingested bacteria in the subsequent meal was considered an important protective mechanism. The same intra-gastric environment produced by the fruit premeal could rapidly acidify and alter protein complexes capable of causing supersensitive reactions in susceptible persons. The influence of this mechanism on food allergy must be investigated by clinicians familiar with this field. We have shown that the gastric content after a fruit premeal can rapidly render the sensitizing substance non-antigenic or non-allergic.

Holmes, Pigott, Sawyer and Comstock (8) and later Comstock and Eddy (9) studied the effect of vitamin A on absence due to illness among industrial employees. The first named group used cod liver oil, but Comstock and Eddy used banana and milk, and their work, therefore, is in fact a fruit-milk premeal study in which factors other than the vitamin A of these foods is a possible factor in the reduction of illness that both studies show.

Haggard and Greenberg (10) have investigated the problem of diet in relation to physical efficiency, and have concluded that between meal feeding increases physical efficiency. They report a freedom from a feeling of fatigue, irritability and from muscular inefficiency when their subjects ingested food at more frequent intervals than the standard three meals a day. The three meal feeding habit of man is not considered physiological by these observers. In addition to muscular efficiency and muscular effort, Haggard and Greenberg investigated efficiency in relation to blood sugar level and respiratory quotents. The following quotation from the above workers illustrates the relative importance of the premeals or between meal. "Our conception of the 5-meal-a-day schedule calls for the conventional 3 meals with the addition of 2 smaller meals: mid-morning and mid-afternoon lunches. But on such a schedule, as on any other, no one meal stands alone in the diet; each is merely a part of the total daily intake of food and should be planned with the total in view. From the dietetic point of view, the food eaten at the 2 extra meals is not to be added to that of the regular meals, but subtracted from them; it is merely eaten at another time. Due provision must thus be made that the selection of food for the smaller meals is properly supplementary to the larger meals."

The "between meal," or as we have termed it, premeal, seems to have received attention from various angles within the last couple of years. The vitamin, calcium, etc., content as supplementary feedings, the influence upon physical efficiency and their possible significance from the viewpoint of efficient gastro-duodenal bacterial killing function as well as aiding in reducing food allergeries.

The gastro-duodenal bactericidal mechanism has been studied in this laboratory for several years. Our primary interest in the fruit premeal was to study its effect upon this mechanism. During the course of the investigation, Bergeim has shown a bactericidal action in the large intestine which can in part be explained by the presence of butyric acid. Bergeim has already shown these substances exert a bactericidal action in *in vitro* experiments. There are then at least two bacterial controlling mechanisms, the gastro-duodenal, depending to a great extent upon hydrochloric acid secretion by the stomach with complete saturation of the gastric contents with acid. The bacterial controlling factor in the large intentine is dependent upon the presence of butyric acid and the more acid contents, which are associated with a lower bacterial count of the washings from the large intestine.

Newer Interpretations of Gall Bladder Function and Their Diagnostic and Therapeutic Application*†

By

MAURICE FELDMAN, M.D.‡

and

SAMUEL MORRISON, M.D.§

BALTIMORE, MARYLAND

IN a previous communication one of us has described some anatomic changes that occur in the filled gall bladder as shown by cholecystographic study. This method of examination also lends itself admirably to an understanding and correlation of the physiologic changes. The physiologic mechanism of contractility of the gall bladder has been studied by many investigators, notably by Boyden (1), Whitaker (2), Ivy (3), Graham (4) and others.

In a recent presentation on the subject of cholecystography a plea was made for a uniform and simple technic (5). In the present study we have further simplified the test by diminishing the time interval following the fat meal. We have selected in this study a group of 61 cases in which poor contractility or an absence of contraction of the gall bladder was observed following a fat meal.

The fat meal utilized, consisted of two eggs and a glass of milk, mixed in a shaker and given as a milk-shake. In order to be certain that a uniform meal of sufficiently high fat content is taken, the meal is administered by the technician. The roentgenologist is then assured that the patient has taken the meal, that it has been retained and furthermore admits of a correct estimation of the meal interval. An attempt will also be made in this publication to correlate the roentgen findings of our cases with the clinical manifestations and the results obtained from the examination of the bile following non-surgical biliary drainage.

The importance of determining the degree of contractility of the gall bladder in a cholecystographic study is emphasized, since, according to our experience, disturbance of this function often produces a train of digestive symptoms and changes in the gall bladder bile which point to pathology of this organ and also to a method of successful therapy in many instances.

For many years it has been known that following the ingestion of certain foods, a definite effect upon the contractility of the gall bladder is produced, causing it to empty.

There is no unanimity of opinion among roentgenologists as to the optimum time interval for the examination following the administration of a fat meal. Although many roentgenologists have chosen the one hour period, others have made the examination at varying periods ranging from one to three hours.

Normally, the gall bladder when filled with an opaque medium, will show an appreciable contraction following a fat meal. The initial contraction begins in from five to fifteen minutes, reaching its initial maximum contraction in thirty minutes. The degree of contractility of the normal vesicle is usually marked, the volume diminishing to less than half, most often to between one-third to one-twentieth of its original size, while in the pathologic state the degree of contraction is lessened to a marked degree and frequently little or no contraction occurs, depending no doubt, upon the

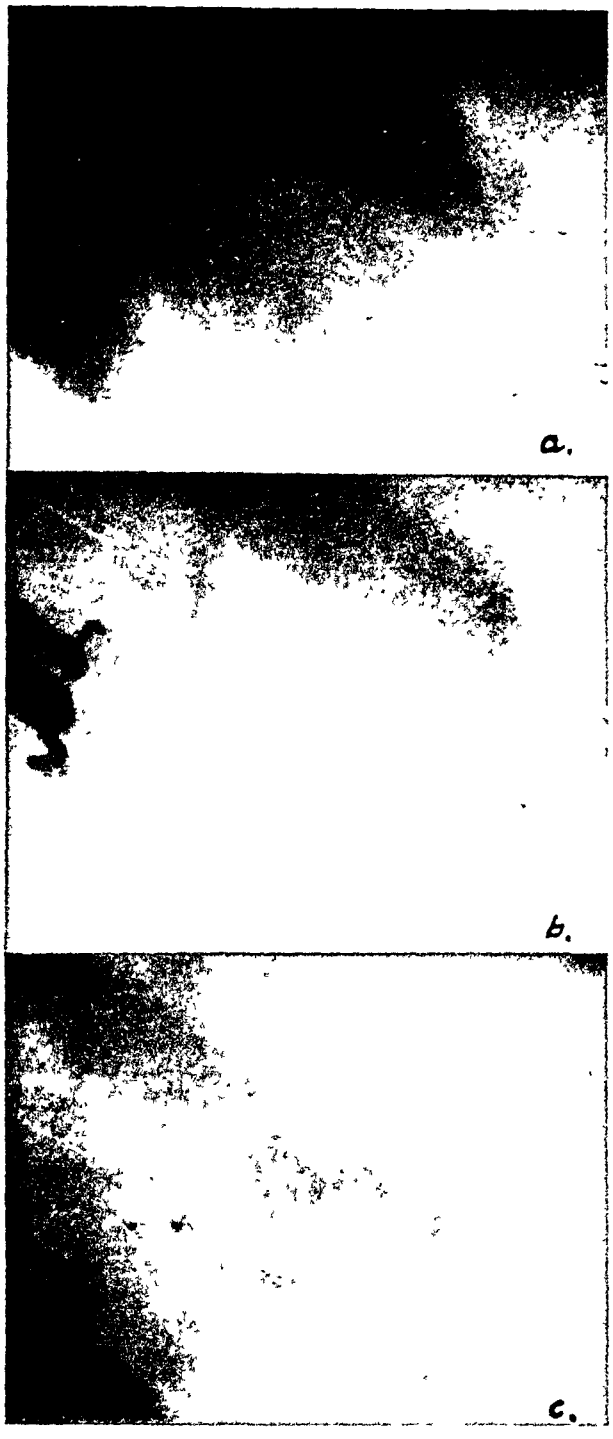

Fig 2. Illustrative case. (Miss M. M.) Showing no contraction following a fat meal. a. Dilated non-calculous gall bladder. b. 30 minutes following a fat meal, no response shown. c. One hour following a fat meal, showed no contraction of the gall bladder.

contracted to two-thirds and two to three-fourths of its original size. Our experience has shown that the roentgenologic examination one-half hour after a fat meal usually suffices. The test is completed after this period, thereby lessening the time consumed in the examination. Examinations of longer periods may be carried out if desired.

As a result of this study, hyperirritability of the gall bladder suggested itself. It probably represents another type of gall bladder dysfunction, characterized by a too rapid emptying. For some years we have routinely made examinations of the gall bladder one hour after a fat meal and in many instances have found the vesicle to be empty of its opaque medium, though the majority of cases showed a vesicle shadow. Just why a small percentage of gall bladders become non-visible was never quite understood. One of the reasons may have been the one hour examination, which is too long an interval for the study of functional disturbances. Thus, in a group of 302 cases of well filled gall bladders, 47 revealed an absence of shadow one hour after a fat meal. No abnormal interpretation was made of this finding as it had occurred in a normal appearing gall bladder. We believe, however, that when the vesicle shadow becomes invisible one-half hour after a fat meal, in a gall bladder which fills normally, one is justified in interpreting this finding as a hyperirritable condition of the gall bladder. Complete emptying of the vesicle as evidenced by absence of the gall bladder shadow one-half hour after a fat meal is an uncommon observation. It occurred in only one instance in another group of cases which are not considered in this presentation.

Clinical study: The non-calculus gall bladder in which the cholecystographic study shows slow emptying does not produce attacks of pain as one sees in gall bladder colic nor is it associated with atypical attacks of pain. Gas is a very prominent symptom, manifesting itself in the form of belching, abdominal distention and pressure sensations. Epigastric distress and discomfort and soreness in the right upper quadrant are very common. Other symptoms which occur fairly frequently are constipation, "acidity," bitter taste, dizziness and nervousness. Inasmuch as there is usually no duct obstruction, jaundice is not observed, but there is enough disturbance in the biliary system to produce definite symptoms. Bile in the urine is rare in these cases and even when the symptoms were at their height there was no evidence of bilinuria. A striking finding is the hepatic enlargement. It is noteworthy that our records show the liver edge distinctly palpable in 18 cases and the liver distinctly enlarged in six; in thirty-seven it was not palpable.

Sex: There were thirty-seven females and twenty-four males in this series. The ages ranging from 21 to 70 years. It is noteworthy to observe that the largest percentage occurred between the ages of 40 and 50.

Duodenal drainage findings: Of the sixty-one cases in this series biliary drainages were obtained in twenty-one instances. In twenty, the bile was turbid, cloudy, and stringy mucus intimately mixed with the bile was found in abundance. In only one instance was the bile recorded as clear, but this drainage was incomplete. Only an occasional w.b.c. was seen and rarely crystals. There was always an excessive flow of thick mucus in the cases drained and sometimes the mucus was so thick that the drainage tube became obstructed. It is of interest to note that of the twenty-one cases drained, relief of symptoms was observed in eighteen instances, while in three no relief was noted. The presence of abundant mucus in these cases would suggest that the term "mucus cholecystitis" adequately expresses the condition and may give some conception of the mechanism of poor contractility. Frequently

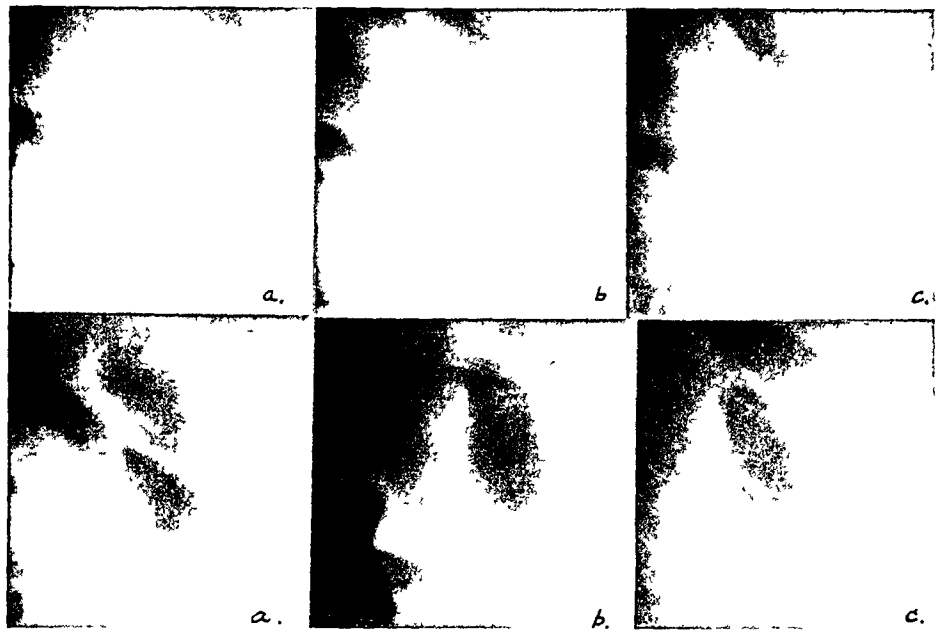

Fig. 3. Upper; a. shows a normal appearing non-calculous gall bladder. b. 30 minutes following a fat meal, gall bladder contracted to ¾ of its original size. c. One hour examination, no further contraction occurred. Lower; a. normal appearing gall bladder. b. 30 minutes following a fat meal; very little change in size is shown. c. One hour examination, size of gall bladder similar to that observed in 30 minute roentgenogram.

these cases are difficult to drain at first, but after repeated attempts and stimulations with magnesium sulphate they begin to drain. Later, the length of time or duration of the drainage is diminished and even though mucus may still be obtained, it apparently flows more readily and less tenaciously; the patient feels better. In one of our cases, the patient had had two gall bladder visualization tests before we saw him. In each instance the gall bladder was reported as not being visualized. In our hands it did visualize (larger dose of dye); it was found to contract poorly following a fatty meal. This patient was also difficult to drain, principally because mucus plugs formed in the tube. After many drainages his biliary system now empties in one hour, whereas formerly with more intense stimulation the drainage was hardly complete in three hours.

The usual sequence of events is as follows: only mucus and duct bile can be obtained at first, later liver bile and only after many trials is gall bladder bile obtained. Abundant mucus is secured with the gall bladder bile and later it becomes normal appearing "B" bile.

In the cases of the poorly functioning gall bladder presented in this study, the appearance of an excessive amount of thick stringy bile was a striking feature which was constantly present. This thick stringy mucus accounts for the variable cholecystographic changes which sometimes occur. It is not unusual in these cases to obtain a non-filling gall bladder during the stage when symptoms are active, while after the condition has subsided, the gall bladder will fill readily. This occurred in one of our cases which revealed excessive amounts of mucus.

CONCLUSIONS

1. The normal human gall bladder shows an initial maximum contraction within thirty minutes after a fat meal. After the second thirty minutes (one hour

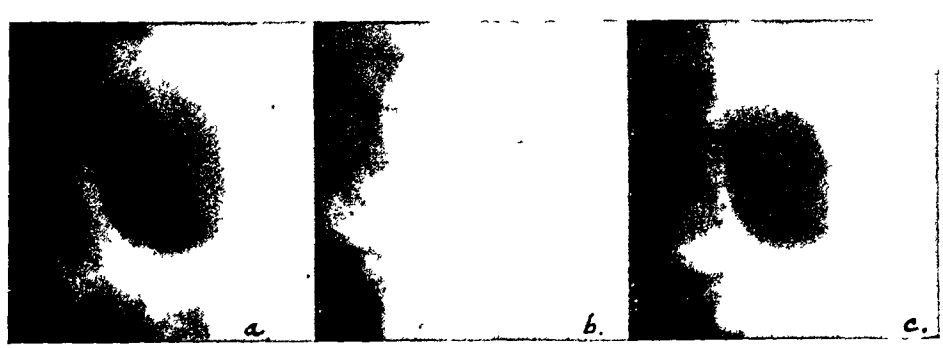

Fig. 4. a. A well filled non-calculous gall bladder. b. Poor contraction 30 minutes following a fat meal. c. Shows slight change in shape of gall bladder with but little further contraction one hour after the fat meal.

examination) very little or no further contraction occurs.

2. Our study would indicate an intermittent contraction of the gall bladder as a normal phenomenon.

3. In the routine cholecystographic test, the thirty minute examination following the fat meal usually suffices; this lessens the duration of the test.

4. The irritable gall bladder is discussed. This term is applied to the gall bladder which empties completely within one-half hour.

5. There seems to be a definite correlation in our series of cases, between the poorly contracting gall bladder and biliary drainage findings.

6. Of the sixty-one cases revealing poor contraction, twenty-one were drained by means of the non-surgical method of Lyon. Of these, twenty yielded abnormal drainage findings as evidenced by excessive amounts of thick mucus.

7. Of the twenty-one drained, therapeutically (i.e. a number of drainages at regular intervals). Complete relief from symptoms was observed in eighteen instances; in only three there was no relief.

8. For the type of affection being discussed, duodenal drainage is the treatment of choice, although surgical intervention sometimes may be indicated.

9. We have discussed a group of sixty-one non-calculus malfunctioning gall bladders and have suggested that the term "mucus cholecystitis" may be descriptive of those cases in which large amounts of mucus are obtained following non-surgical biliary drainage.

Clinical Results in the Medical Treatment of Chronic Ulcerative Colitis*

By

EVERETT D. KIEFER, M.D.

BOSTON, MASSACHUSETTS

IT is singularly difficult to compare the results of various forms of treatment for chronic ulcerative colitis because one of the chief characteristics of this disease is the variable severity of its manifestations. Furthermore, this variation in severity is probably the most important factor determining the final outcome of an individual case. For this reason, patients with ulcerative colitis who are observed in this Clinic are classified into three fairly distinct clinical groups for the purpose of studying the end results of treatment.

In Group I, are placed all cases which show no evidence of toxemia or systemic manifestations of colitis such as fever, leukocytosis, anorexia or vomiting. In grouping cases, no attention is given to the extent of the disease in the rectum and colon for two reasons: first, the limits of the morbid process as determined by the X-ray are uncertain, and second, close correlation between the clinical severity and the amount of colon involvement has not been observed.

In Group II, are placed those cases which, although they show no signs of toxicity, are found on examination to have marked permanent and irreparable damage of the colon, rectum or both. Patients with rigid contracted or stenosed bowels from long standing colitis fall into this group. Secondary anemia caused by chronic blood loss is not considered a sign of toxicity.

In Group III, are placed all patients who have fever or show other clinical evidence of toxemia, such as leukocytosis, nausea, vomiting, rapid pulse rate and prostration.

MATERIAL STUDIED

Fifty-five cases of ulcerative colitis observed and treated medically at this Clinic, were found to fall into the above classification as follows:

Group I (non-toxic, non-sclerotic)	23
Group II (non-toxic, sclerotic)	8
Group III (toxic)	24

The *treatment of ulcerative colitis* in this Clinic, has been the management of a chronic disease involving an inflammation of the rectal and colonic mucosa with varying systemic effects. Therefore, except in a small proportion of cases in which so-called "specific" vaccines and sera have been tried, the treatment has been essentially non-specific in character.

Rest in bed has been considered essential and a large proportion of the patients were treated for a time in the hospital.

The *diet* prescribed varied with the individual but in general was bland and contained comparatively little residue. Boiled milk was the basis of the diet in many cases, while in others milk appeared to increase the

number of stools and the patients did better when milk was omitted. Meats, such as beef, lamb, liver and chicken were allowed early in the management. The vitamine content of the diet was fortified by the use of cream, butter, brewer's yeast, cod liver or halibut liver oil and orange juice. In some instances it was necessary to give consideration to food idiosyncrasies.

(1) Mulford's antibody globulin.

(2) Vaccine from another case.

Of the *drugs* used, bismuth and belladonna were most frequently employed. Opium was found useful in the severe cases. In many instances, it seemed advisable as a therapeutic test, to employ a course of antiamoebic drugs such as emetine, chiniofon or acetarsone. These drugs were used cautiously and on any indication of aggravation of symptoms their use was discontinued. Some patients appeared to be improved by acetarsone but it was impossible to conclude that this or other arsenicals had any definite value.

Colonic irrigations were not used in this group except for small amounts of yatren or tannic acid solutions which were instilled into the rectum in a few cases. Small starch and opium enemas were of some value in alleviating tenesmus.

For the secondary *anemia* which frequently occurred, iron, in the form of ferric ammonium citrate, Blaud's pills or ferrous sulphate, was administered. In the severe cases blood transfusions were used freely and parenteral injections of saline and glucose solution were extremely valuable.

Dilute *hydrochloric acid* was given with meals if an achlorhydria existed.

Surgical interference, in the form of transverse ileostomy, was resorted to only in those cases with increasing toxemia and were definitely failing under

medical treatment. As a life saving measure it was apparently deferred too long in some of the fatal cases. Even if done early, in some of the extremely severe, fulminating forms of the disease, it is improbable that ileostomy would have prevented death.

Particular attention was given to the *general hygiene* of patients with ulcerative colitis. *Foci of infection* were searched for and treated. After leaving the hospital, patients were warned to avoid indiscretions in diet, fatigue and acute infection.

To speak of cures of this condition appears to be presumptuous as it does not take into account the characteristic tendency to spontaneous remissions and exacerbations.

The best results are therefore designated as complete and continued remissions. The next most satisfactory cases are those who obtained complete remission of symptoms but later have had a mild recurrence from which they recovered and are clinically well at this time. A third group also considered to be satisfactory end-results are those patients who are greatly improved and are carrying on their occupations but still have some evidence of colitis such as four or five loose stools daily.

The *unsatisfactory results* include patients who were completely relieved by treatment but later suffered a severe and disabling recurrence, or those who received no appreciable benefit from treatment, or those who died of the disease while under treatment.

Although so-called *"specific" forms of therapy* were used in twelve cases, it was found difficult to determine their value. Vaccines were prepared from organisms recovered from stools of cases of ulcerative colitis which conformed morphologically and culturally with the organism described by Bargen as the specific etiologic agent. Hypodermic injections of vaccines in gradually increasing doses were carried out over considerable time in a few cases.

In a few of the acute toxic cases anti-ulcerative colitis serum now on the market was employed without convincing benefit.

The cases observed in this Clinic are grouped in the accompanying tables according to their clinical classification and according to the type of therapy they received. Tables No. 1 and No. 2, show that the prognosis of chronic ulcerative colitis in the mild, afebrile and uncomplicated form is excellent. Seventy-six percent of this group recovered under non-specific therapy. Since only two cases were treated with vaccines the place of this therapeutic measure was not sufficiently evaluated. However, the recovery of these two cases brings the percentage of good results in this type of case up to 78.

Table No. III demonstrates that one-half of patients with irreparably damaged bowels can be relieved by non-specific measures. It is surprising that normal bowel function can be even approached with the

amount of scar tissue that may be present in the intestinal wall of patients in this group.

It is in the third or the toxic afebrile group that the poor therapeutic results and the mortality of ulcerative colitis become apparent. In Table No. IV is shown that with non-specific therapy in only 38% of cases can results be called satisfactory. The mortality in this group of sixteen cases was 25%. In Table No. V the results in eight cases in which "specific" vaccines or anti-sera were used are tabulated. Two patients in this group who received vaccine recovered but anti-serum failed to save any of those in which it was tried. A remission occurred in Case No. 33353, following vaccine medication but a severe recurrence which was not relieved by serum necessitated an ileostomy. The mortality of this group of eight cases was 62%.

The *collective results* of the entire series studied (55 cases) are as follows:

Satisfactory	30	(55%)
Unsatisfactory	25	(45%)
Total	55	
Deaths	10	(18%)

DISCUSSION

A comparison of our results with those obtained in other Clinics using "specific" or other forms of therapy is impossible. The clinical results reported in this paper indicate that the end-results of treatment are profoundly influenced by the relative distribution of cases in the three groups just described. This relative distribution may depend largely upon the diagnostic criteria used in differentiating between early, mild, ulcerative colitis and other forms of colonic irritation. Furthermore, if, by chance or by other reason, a relatively large number of very sick patients is treated the end-results will be more unfavorable regardless of the form of therapy employed.

Therefore, it is hoped that future reports on the results of various forms of treatment of ulcerative colitis will include some clinical classification of the cases similar to the one described here.

It is well known that a considerable proportion of all cases suffering from chronic ulcerative colitis have the disease in a comparatively mild form. Although this group complains of bloody diarrhea and show on proctoscopic examination the characteristic inflammatory reaction of the mucosa, the condition is essentially local. Clinical signs of systemic manifestations of the disease, such as fever, leukocytosis or prostration, are usually lacking. The remaining cases of ulcerative colitis are characterized by abundant clinical evidence of systemic effects of the disease. Fever and other signs of toxemia are present in some cases from the onset, while in others they may be preceded by a period when only local signs were manifested.

It is interesting to speculate on the significance of these two groups. The existance of the afebrile group suggests that ulcerative colitis may be originally a non-infectious disease and that the onset of fever and toxic signs indicates the point when the resistance of the bowel mucosa is so broken down that secondary invasion by organisms within the intestine takes place.

It must be admitted, however, that convincing proof either for or against this concept is lacking.

SECTION VI—*Abdominal Surgery*

A Review of 746 Gastric and Duodenal Ulcers*

By

J. WILLIAM HINTON, M.D., F.A.C.S.†
NEW YORK, NEW YORK

IN discussing the treatment of gastric and duodenal ulcers the question of gastric ulcer undergoing malignant degeneration has such an important bearing on both the medical and surgical management of this type of ulcer that one should state his views on this point. The opinion expressed by me is dictated by observation in the stomach clinic of the 4th Medical and Surgical Division at Bellevue Hospital. During the past eight years we have observed 746 ulcers and 10 carcinomas of the stomach or a total of 756 cases. Of the 746 ulcer cases 642 were duodenal and 104 gastric or a percentage of 14 per cent gastric as compared with duodenal ulcers. If the 10 gastric carcinomata are added to the gastric ulcers we have 114 gastric lesions and of these only 8.7 per cent are carcinoma. From a practical point of view the emphasis of gastric ulcer becoming malignant has been over stressed. In another communication (1) this subject was more fully considered. It is worth remembering that primary carcinoma of the duodenum does occur, but, so far there has never been a reported case of duodenal ulcer undergoing malignant degeneration. If ulcer is such a common forerunner of gastric carcinoma then

*Read before the Lancaster County Medical Society, November 6, 1935.
†Assistant Attending Surgeon, New York Post-Graduate Hospital; Associate Visiting Surgeon, Bellevue Hospital.
Submitted December 9, 1935.

it should occur occasionally in the duodenum. A review of the literature (2) has failed to reveal that it does occur.

The etiology of ulcer is unknown in spite of the vast amount of experimental work that has been done in recent years. There are certain factors that influence the development of peptic ulcer and these will be discussed.

Sex: It is a disease that affects the male more frequently than the female. This has been most forcibly brought to the attention of the medical profession in (3) the Quarterly Bulletin of the Department of Health of New York City issued in 1934 in which they analyzed the death rate from ulcer patients from 1900 to 1933 and found that the ratio of those dying from an ulcer in 1900 was one male to one female, which very strikingly emphasizes the marked increase in the incidence of ulcers in the male sex. Age: An ulcer may affect a patient at any age from childhood to senility. The most common period in which ulcers are noted is the period between thirty and forty years of age. In analyzing 671 cases of peptic ulcer admitted to the stomach clinic of the 4th Medical and Surgical Division at Bellevue Hospital we found (4) that 47 per cent of the patients afflicted with ulcer sought relief between the ages of thirty and forty years. Heredity: Ulcers do run in families. We have had as many as one brother and three sisters suffering from ulcers out of a family of five. It is not uncommon for a parent and child to present themselves for treatment. Occupation does not seem to play any part in the causation of an ulcer and when one analyzes a large series of cases it is noted that people in every walk of life from high executives, small business men, truck drivers to longshoremen suffer from this disease. Ulcer is definitely on the increase. Although we are not able to say what causes an ulcer we can tell you that your chance of developing an ulcer is greater than twenty-five years ago. I can prove that statement in two ways. When one takes the total number of ulcers admitted to Bellevue Hospital each year and compares it year by year from 1910 to 1935 with the total number of patients admitted each year one sees a gradual increase in the number of ulcer patients per year and when it is figured against the total admissions per year the percentage of ulcers increases yearly. In 1910 there were 33 ulcer patients admitted to Bellevue Hospital and there were 36,000 patients admitted that year. In 1934 there were 353 ulcer patients as against 59,000 admissions. If one adds the ulcers from 1910-1922 admitted to Bellevue Hospital it is found that ¼ of 1 per cent of the patients had ulcers. From 1922-1934 it is found that over ½ of 1 per cent of the patients had ulcers. In other words your chance of developing an ulcer has doubled in the past twenty-five years. The Department of Health Bulletin in 1934 gives the following death rate of peptic ulcer per 100,000 population: In 1900 the rate was 3.69 while in 1933 it was 6.77. In other words those that died from peptic ulcers in New York City has doubled from 1900-1933.

The diagnosis of a peptic ulcer can be made nearly as accurately from a carefully elicited history and physical examination as by rontgenological studies of the gastro-intestinal tract. Of course both are essential in the diagnosis and treatment of a patient suffering from an ulcer, but one should not be mislead by a negative rontgenological report in a patient with epigastric pain that radiates to the back or in a patient with tarry stools or hematemesis. It is well to emphasize that posterior duodenal ulcers are the ones that cause a rather severe pain which is referred to the back and also this type of ulcer frequently causes severe hemorrhage. In a high percentage of instances it is difficult or impossible for the rontgenologist to demonstrate the lesion in view of the fact that it is on the posterior portion of the duodenum and frequently adherent to the pancreas. Therefore, clinical experience must be combined with careful laboratory studies in the diagnosis as well as in the advise for the method of treatment to be followed by the patient with a peptic ulcer.

The treatment of a peptic ulcer is generally conceded by both internists and surgeons to be medical as long as symptomatic relief can be obtained by medical management. It is well worth stating that there is definite danger in prolonged medical treatment when symptomatic relief is not obtained. In the treatment of peptic ulcer one should remember that ulcers of the stomach respond more rapidly and more lastingly to medical treatment than do duodenal ulcers. From the experience we have had during the past eight years I feel that the chances of a gastric ulcer undergoing malignant degeneration is very slight. It is important to emphasize that at times it may be difficult to differentiate between a carcinoma and an ulcer of the stomach. If the patient is past middle life and the X-rays are suspicious of malignant degeneration then one is justified in treating the patient as a possible carcinoma. These instances of confusion between an ulcer and carcinoma are relatively infrequent in a large clinic. A gastric ulcer, if it be an ulcer, will usually respond rapidly to medical management and the patient will soon become symptom-free. On the other hand, if the lesion is a gastric carcinoma medical management will not give satisfactory symptomatic relief under dietary management. One should remember that duodenal ulcer occurs six to one in comparison with gastric ulcer.

It is not necessary to go into a detailed discussion of the dietary management but we follow the Sippy regime in our clinic. It is of course necessary for one to adhere to a diet for years if permanent relief is expected. Medications are not given in the clinic unless the patient does not respond on a restricted diet. Alkalies are used when indicated and we have used other medications such as gastric mucin, synodal, larostidin, vaccines both non specific and specific, foreign proteins, such as aolan and all have had a rather extensive trial. The different medications occasionally have a definite beneficial result but there is nothing specific in any ulcer medication that we have had the occasion to use. At the present time we have just begun using silicon dioxide following the work and suggestion of Dr. Henry Lee of the University of Cincinnati and it may be more beneficial than other medications.

It is essential to insist that any focus of infection be eradicated, including bad teeth, tonsils, or sinus conditions. It is not believed that these have any direct etiological bearing on the ulcer but they lower the general resistance of the individual and therefore make it more difficult for him to overcome the ulcer from which he is suffering. Also it is important that

the patient get at least nine hours rest a night and avoid as much excitement and tension as possible. Also obstaining from the use of tobacco is quite essential and alcohol should be used in moderation if not completely avoided.

When a patient ceases to be a medical problem and should be operated upon constitutes one of the most difficult decisions to make in an ulcer patient. We do not believe that a patient presenting himself for treatment with a six hour residue of 50 to 100 per cent of the motor meal at the end of six hours is a surgical problem until medical treatment has failed. In our experience about 70 per cent of these patients do satisfactorily if put on anti-spasmodic and Sippy diet. Most of the retention is due to a persistent pyloro-spasm and edema which is frequently overcome with belladonna and dietary management. Hemorrhage does not constitute an indication for surgery except in a selected group of patients and the classification of the hemorrhaging ulcers that we use seems to be of some practical value in the treatment of bleeding ulcers and therefore it will be given. They are divided into five groups: (1) Hemorrhage occurring in patients with peptic ulcer under competent medical management; (2) hemorrhage in cases operated upon for an acute perforation, or chronic ulcer, that has never hemorrhaged until months or years following operation; (3) hemorrhage occurring in ulcers that had previously been operated upon for hemorrhage and the patient has continued to have recurring hemorrhage postoperatively; (4) severe hemorrhage that has occurred in patients with negative, or very short gastric histories, and the patient never knew that he had an ulcer until the hemorrhage occurred; (5) patients admitted with hemorrhage and a long history of ulcer symptomatology but without regulated medical treatment.

In outlining the management of a severe hemorrhage it is most important to consider the history and clinical course of the patient. Obviously, in the first group of cases, surgical intervention is desirable after the patient has recovered from the acute hemorrhage and is properly prepared for operation. A fatality in this type of patient is unusual, but the diability from recurring hemorrhages constitutes a most discouraging problem from the patient's point of view. In the second group we have a more difficult condition to treat, as the patient has either had some form of excision, gastro-enterostomy or gastric resection; and unless these patients have had two or more hemorrhages a reoperation should not be considered as the hemorrhage has occurred in spite of previous surgery, and possibly as a result of the surgery; therefore, one cannot give the patient much assurance that the same thing may not recur. In the third group we have the most difficult type of patient to treat with which one is confronted. Some of these patients have had several operations, including resection, and in spite of multiple operations have continued to bleed, and for that reason one should hesitate before reoperating upon these patients in the hope of relieving a hemorrhage unless a definite marginal ulcer can be demonstrated, which is usually not done. In group four it can be seen that the patient may have a severe hemorrhage and die suddenly, although one should not infer that because a patient with a negative, or short gastric history before the hemorrhage occurs, will have a fatality as a result of it. This is the type of patient one is undecided whether it is best, after giving repeated transfusions, and the patient's condition is considerably improved, to operate or treat conservatively. When one operates early in this type of case the ulcer must be excised, even if a gastric resection has to be done; otherwise a surgical intervention is of no avail.

In the fifth group we encountered more misunderstanding than in any other because the surgeon usually thinks that the long history, plus a hemorrhage, warrants surgery, but such is not the case. These patients have not received any regulated medical care and it is unusual for them to be admitted for a second hemorrhage. The results from conservative treatment have been sufficiently encouraging not to recommend operation in the first hemorrhage.

The one indication for operating upon a patient with an ulcer is pain which cannot be overcome by any methods of medical management and persistent pain in a patient under adequate medical treatment means that the ulcer is usually adherent to some adjacent viscus. In duodenal ulcers the pancreas is most commonly adherent, but occasionally it may be the liver and in gastric lesions it can either be the pancreas or the liver. When an ulcer becomes adherent to an adjacent viscus it constitutes a definite indication for operation and that can only be determined by clinical course of that case. When one evaluates the pain from which the patient is suffering it is found not to be of the ulcer type but is more severe and penetrating and the intensity usually necessitates sedatives to sleep.

When one has reached the decision that a patient needs to be operated upon for an ulcer we are faced with what type of operation to advise for a peptic ulcer. Everyone is aware that the majority of authors advocate either pyloroplasty or gastro-enterostomy and report most excellent results from both. In considering operation I wish to call attention to a previous communication (4) from our clinic in which 114 postoperative cases were reviewed and I am giving at this time three tables taken from that report.

TABLE V

Why Was the Patient Operated?

Symptoms	Number	Per Cent
Uncontrollable pain	85	79
Obstruction associated with pain	10	9
Bleeding associated with pain	8	8
Obstruction alone	4	3
Obstruction and bleeding	1	1

TABLE VI

Type of Operation

Type		Number	Per Cent
Gastro-enterostomy with excision	2	85	77
pyloroplasty	1		
enterostomy	2		
Resection including dissociation of old gastro-enterostomy	2	11	10
Pyloroplasty		7	6.5
Simple excision		5	4.5
Dissociation		3	2

TABLE VII
End Results

Condition Cured	No. of Cases	Per Cent
Gastro-enterostomy	33	
Resection	4	
Pyloroplasty	1	
Excision	1	
Total	39	37
Benefited		
Gastro-enterostomy	10	
Pyloroplasty	2	
Dissociation	1	
Total	13	12
Unimproved		
No relief under one year	23	
Developed marginal ulcer	16	
Temporary relief with return of previous symptoms	13	
Died (ulcer complications)	3	
Total	55	51

These tables will readily show that our results from the conservative type of operation has been anything but encouraging. It is also worth while to draw your attention to the high frequency of gastrojejunal or marginal ulcer which we have encountered in the cases which we have followed. In another communication (5) for the first six years of our clinic we reported an incidence of 16.4 per cent of marginal ulcer following gastro-enterostomy. One may think we have used poor judgment in selecting our cases, but of the 746 cases we have observed in the clinic 577 cases were unoperated upon when registered for their first visit. Of this number only 61 or 10 per cent have been referred for operation which would indicate that we have used reasonable care and discretion in selecting our patients for operation. Of the 746 cases which we have had in the clinic they have made 13,996 visits which averages 18 visits per patient during this period, which would give us reasonable opportunity to personally observe and direct the regime for each patient to follow.

Unquestionably the type of operation that is done must rest with the individual operator and the indications that he encounters at the time of laparotomy. From our cases the most common condition that is associated with a duodenal ulcer is a chronic pancreatitis, and if the chronic pancreatitis exists a gastro-enterostomy is a most unsatisfactory procedure for the relief of pain. Therefore, I feel a sub-total resection is warranted in such cases. Also bleeding duodenal ulcers are more commonly encountered in the posterior portion of the duodenum, than in the anterior and for that reason excision of the ulcer is essential to effect a cure. That can only be brought about by a sub-total resection if the ulcer is placed on the posterior portion of the duodenum and adherent to the pancreas. In patients suffering from pyloric obstruction with a large dilated stomach, a gastro-enterostomy is a quite adequate operation but even in this type of case a marginal ulcer does occur. If then one operates upon the patient with a duodenal ulcer that is having repeated hemorrhages or a duodenal ulcer associated with chronic pancreatitis, a sub-total resection is the operation of choice. The mortality in a resection is no higher in the hands of those that have a reasonable experience in gastric surgery than is the general mortality following gastro-enterostomy at the present time.

Electro-Cholecystocausis*

Preliminary Report

By

LESTER R. WHITAKER, M.D.†
BOSTON, MASSACHUSETTS

THE acutely inflamed gall bladder presents a difficult problem to the surgeon. Immediate operation is dangerous on account of hemorrhage. Prolonged expectant treatment, unless the patient is improving, may lead to rupture of the gall bladder. Cholecystostomy, heretofore the procedure of choice in these cases, leaves a diseased gall bladder in place and necessitates, for the future welfare of the patient, a cholecystectomy. A method whereby the gall bladder could be treated at the time of cholecystostomy in such a manner as to lead to its obliteration, would avoid the danger of a second operation. Such a method by the use of electrosurgery has been devised, and is now being tested on animals.

METHOD

In dogs, at a preliminary operation, the gall bladder is traumatized by crushing with clamp. Three to five days later the wound is reopened. The inflamed gall bladder is attached with sutures to the abdominal wall, an opening made in the fundus, the contents evacuated. With the aid of a focussing headlight and special re-

*Electrosurgical cauterization of the gall bladder. For this term the writer is indebted to Paul J. McManus, S. J.
†From the Evans Memorial for Clinical Research and Preventive Medicine of the Massachusetts Memorial Hospitals, Boston.
Submitted January 6, 1936.

tractors the whole mucosa of the gall bladder is thoroughly treated by fulguration and light contact coagulation.

It is essential that the whole mucosa of the gall bladder be destroyed by this process, otherwise regeneration will lead to formation of a permanent sinus. But it is also necessary that perforation of the gall bladder as a result of deep contact-coagulation be avoided. Thus the application of electrosurgical current must be through fulguration and light surface coagulation only. The heat from fulguration is intense, but localized and superficial. It is deep enough, however, to destroy the mucosa. The blackening by the charring effect of fulguration is an indicator as to the thoroughness of treatment. Drains are placed within the gall bladder; the sinus is allowed to heal slowly, and close by sclerosis.

RESULTS

In experiments with dogs (eight in number) the sinus has closed at the end of three to four weeks; and post-mortem examination has shown that the gall bladder has been obliterated. No damage to other structures has been observed.

Electro-cholecystectomy has been described previously (1, 2, 3). It was a modification of Pribram's (4) operation of "mukoklase," in which the gall bladder was split to the cystic duct, the mucosa treated with an ordinary cautery, the leaves of the gall bladder whipped together with sutures, and the abdomen closed without drainage. In electro-cholecystectomy the redundant portions of the gall bladder are trimmed away and the part remaining attached to the liver treated by fulguration and light contact coagulation. Contrary to Pribram, however, drainage is employed.

Thorek (5, 6, 7) has devised a procedure termed "cholecystelectrocoagulectomy," using deep contact coagulation instead of fulguration of the part of the gall bladder left attached to the liver; and peritonization of the tied stump of the cystic duct and the coagulated tissue on the gall bladder bed. He also does not drain.

Electro-cholecystocausis, as described, appears to be an original procedure, though chemicals like phenol have been used for cauterization of the gall bladder (8). Experiments indicate that the method carries very little risk, is not too difficult of application, obliterates the gall bladder by a procedure carried out with little more shock than cholecystostomy, and avoids the danger of a second operation.

The Technique of the Local Injection of Saline Solution for the Relief of Pruritus Ani*

By

WILLIAM J. SCHATZ, M.D.

and

VAUGHAN SPRENKEL, M.D.

ALLENTOWN, PENNSYLVANIA

THIS communication presents the technique of the local injection of physiological saline for the relief of pruritus ani. This treatment has been devised by the senior author and has been mentioned in another communication although the technique has never been described in detail (Schatz, 1). The present paper aims to bring this simple procedure to the attention of the medical profession and, especially, to the general practioner.

Pruritus ani is a most distressing ailment and there is perhaps no affliction more difficult to relieve. Numerous methods of treatment have been suggested for the alleviation of this common complaint. These vary from the more simple measures which include local application of solutions or perirectal injections of phenol solutions (Goldbacher, 2), to the more formidable surgical procedures of severing the sensory nerves supplying the area.

The etiology of pruritus ani is diverse and includes important factors which are as yet undetermined.

*Presented at the thirty-sixth annual meeting of the American Therapeutic Society, Atlantic City, N. J., June 7, 1935.
Submitted November 15, 1935.

The simplest classification of the numerous causative agents is a modification of that adopted by Pennington (3) and consists of two groups. The first includes all local conditions such as trichophyton, irritating anal and rectal discharges and the systemic disturbances as diabetes and jaundice. This group is really that of anal irritation and strictly speaking is to be distinguished from the second group of those with persistent and intractable pruritus for which no demonstrable cause can be elicted. This so-called "idiopathic pruritus ani" is the most frequent and despite the elimination of all known local and general causes, has been remarkably resistent to every therapeutic method. The treatment to be outlined has proven especially valuable in this obstinate group of cases and for this reason should have a particular appeal to the general practitioner.

TABLE I

Treatment of Pruritus Ani. Therapeutic Results Following Local Injection of Sterile Physiological Saline Solution

31 Cases Treated*			
Each Case Received Some Measure of Undoubted Relief			
COMPLETE RELIEF		PARTIAL RELIEF	
16 Cases 50%	Complete relief without recurrence	15 Cases 50%	*6 Cases*—Complete relief with recurrence within 2 to 6 months. No recurrence following second treatment.
			9 Cases—Kept comfortable, despite recurrences, by repeated treatment each 1 to 3 months as required.

*These cases were all of the idiopathic and intractable group of pruritus ani where the elimination of local and systemic factors failed to achieve any measure of relief.

TECHNIQUE

A 10 c.c. syringe equipped with a twenty-three gauge needle, seven-eights of an inch in length, is used for the injection. Sterile physiological saline is the solution employed.

Having placed the patient on an examining table, in the left or right lateral position with the lower leg drawn somewhat backward, the upper hip is allowed to tilt slightly away from the operator. A sheet is draped over the buttocks, allowing an exposure of three inches about the anus. A good source of light is essential, and for this purpose a head-mirror with indirect light will suffice, but better still is a direct source from a small portable "goose-neck" lamp placed to the side of the operator.

Preparation of the entire area is accomplished by cleansing with liquid soap and water after which alcohol is applied. The area is divided into four portions by projecting two imaginary lines through the anus: the first passing antero-posteriorly through the fold of the buttocks and a second extending laterally and at right angles to the first. The greatest pruritic involvement is usually about the posterior anal commissure therefore either posterior quadrant is selected for the initial injection. Consistent with the greater degree of involvement, this quadrant should receive a relatively large volume of the fluid. The site of injection is along the edge of the circumanal pigmented area, which is situated one and one-half inches external to the edge of the anus. After the needle has punctured the skin, the point is directed toward the rectum as the spoke of a wheel. The barrel of the syringe is lowered so that the shaft of the needle lies in a plane of subcutaneous tissue, parallel to the skin and is at right angles to the long axis of the rectum. The needle is inserted until its point approaches within one-half inch of the rectal wall. This method is contrary to the usual injection procedure where the shaft is directed parallel to the long axis of the rectum. Three to five c.c. of the solution are slowly injected. The solution enters the tissues encountering only a slight resistance comparable with that of an intravenous injection and causes no discomfort to the patient. The needle is withdrawn and the procedure repeated employing a somewhat smaller volume in the less involved quadrants until the total of ten c.c. has been injected into the perirectal tissues. A total volume of fifteen to twenty c.c. of solution may be required for cases with extensive pruritic involvement. Following the injection the anal region should be gently massaged by a pledget of cotton saturated with alcohol or disinfectant. This manipulation achieves a distribution of the fluid about the perirectal spaces.

The only sensation following the injection is a faint sense of fulness about the injected area and except for the slight discomfort caused by the introduction of this small gauge needle there is no pain. In hypersensitive individuals anesthesia at the site of injection can be secured by applying a drop of phenol to the skin followed by alcohol, although this is rarely required.

The patient experiences a measure of relief within two to four hours following the treatment. In our series there have been no instances in which some benefit has not been secured. Complete alleviation without recurrence is obtained in about 50 per cent of all cases. In a few instances it is necessary to secure this complete result by repeating the procedure within one week. This is probably due to the fact that the entire involved area was not originally contacted by the solution. Of the remaining cases about one-half have complete relief with a recurrence of the symptoms within two to six months. These usually suffer no recurrence following the second treatment. The remaining group of patients experience an undoubted benefit following the injection and although they are not completely relieved it is possible to keep them comfortable by repeated injections administered from one to three months as required.

This method requires no extraordinary precautions and presents but two remote possibilities for error. The first, puncturing the rectal wall while injecting, is practically impossible providing a seven-eights inch needle is employed and the needle is inserted at the edge of the circumanal pigmented area. The second precaution is only required in males where the urethra can be avoided by not injecting along the mid-line anterior to the commissure. It is doubtful whether the injection of normal saline solution would cause any damage to these structures even though any one of these two errors was committed. There have been no complications following the use of the method and abscess formation has not occurred.

No attempt is offered to explain how this treatment achieves its results although a non-specific mechanism is suggested.

SUMMARY

The technique of the local injection of sterile normal saline solution is presented for the relief of pruritus ani. This procedure is outlined especially for the benefit of the general practioner. No particular instruments, special solutions nor a detailed knowledge of the anatomy are required to secure therapeutic success. The technique is a simple office procedure which is painless and does not incapacite or inconvenience the patient.

A report of thirty-one cases is included.

Annual Abstracts of Protologic Literature

(May, 1934-May, 1935) By CLEMENT L. MARTIN, M.D., Chicago, Illinois

The complete bibliography from which these Abstracts were made will be published in full in the Transactions of the American Proctologic Society, 1935.

COLITIS

Amebic Colitis (see separate heading).
Chronic Ulcerative Colitis (see separate heading).
Irradiation Colitis (see separate heading).
Simple "Colitis," Mucous Colitis (Colopathy, spastic, hypertonic; hyperkenetic; allergic; vagatonic, atonic; reflex, functional; irritable colon, etc.).

Hurst makes the point that the diagnosis "mucous colitis" is often made when the real trouble is achylia gastrica, rectal constipation (dyschezia) abuse of cathartics or enemas and colon irrigations. He urges the use of Ewald's term mucomembranous colic, to separate one entity from true colon inflammation. A congenitally small anus, which he regards as a not uncommon cause of constipation, acquired anal stricture following hemorrhoidectomy, anusitis with or without hemorrhoids, or fissure may be an important factor in some cases. He uses medical diathermy for the relief of these.

Although it was probably known even before the days of doctors that "one man's food was another man's poison," and medicine has for years been familiar with idiosyncrasies to certain foods, more exact information is being acquired. Food allergy is being studied; although to some it may mean anything from the gastro-intestinal stasis and other disturbances occurring in psychopathic states to the intestinal and general toxemia of acute appendicitis, its all-inclusive use is not the fault of the real contributors to the subject. Vaughn regards allergy as a foreign protein reaction, with the underlying mechanism responsible "not so much a pathologic condition as a pathologic exaggeration of a normal physiological response." He points out that the tendency is toward loss of hypersensitiveness and thus recovery and that the average period of necessary avoidance of the offending food is four and a half years. As the knowledge of the protein chemistry concerned in digestive processes advances, food allergy may occupy a less uncertain basis than it now has. Last year in an exhibit on nutrition sponsored by Alvarez, Fitz and Jeans in the A. M. A. Scientific Exhibit a pamphlet was given out containing this statement. "The following foods in the order named were found most often to be the cause of digestive trouble: cabbage, apples, tomato, milk, chocolate, onion, lettuce, coffee, strawberries, eggs, meat, cucumber, sweets, fats, radishes, cheese, cauliflower, peppers, prunes, oranges and salmon. Food allergy is not considered in this list."

Vaughn states the list contains the commonest allergic foods. Because of difficulties in the skin test, *i.e.*, not more than 50% of skin sensitization tests give positive results with the food protein responsible for hypersensitiveness, groups of proteins given as a single test and elimination diets are used.

Krouse thinks a study of colon form and function important considerations in getting a clear idea of the trouble with the patients having simple "colitis"; he favors the term colopathy and limits colitis as Bargen does to definite colon inflammation. He states "the limited benefit resulting from correction of local abdominal and rectal lesions, intestinal flora and allergic intolerances must be admitted. In studying these conditions, the bowel form (length, loopings, decompensation) as well as hypertonia and atonia must be considered."

Eggleston emphasizes that the trouble is not primarily intestinal in origin, but that an anxiety state, in a person having an unstable or poorly co-ordinated nervous system, is primarily the cause of the colon dysfunction; also "that there are those who consider the hypertonic colon an allergic reaction because of its similarity to asthma. Until more is known of the subject of allergy, I think it best to consider it a vagotonic manifestation . . . and that the real cure comes as a result of education rather than some method which may temporarily relieve the constipation."

With due regard for the careful work some students of the condition are doing, the helpful suggestions for further study and for treatment which such work gives, as well as a respectful acknowledgement of the insight indicated in Eggleston's opinion just quoted, and in *Bastedo's* clinic, one can readily see from the foregoing that we can not offer much under the heading of "recent progress in colopathy."

CONSTIPATION

Beck in "The Management of Chronic Spastic Constipation" gives a general review of the subject. Chronic constipation progresses usually through three stages: atonic, catarrhal, and spastic. The latter is perhaps the commonest variety for which the physician is consulted. He lists the causes as constitutional, eating habits, diet, cathartics, neglect, diseases, e.g. of stomach, liver, intestines, anaemia, functional neuroses, and others. Treatment is given in detail. *Spencer* does not hesitate to start his paper with "Constipation is a symptom not a disease," trite though it may be. He considers the subject from the standpoint of the physiology and the pathological physiology concerned. Associated causes may be failure to respond regularly to the urge to defecation, dietary factors, cathartic abuse, sedentary habits, obstruction from bands, and adhesions usually causing right sided stasis; stasis from emotional states, irritating food residues, lead, tobacco, caffein, organic diseases of the lumbar cord and inflamed mucosa, however caused.

In his discussion of spastic constipation he does not support the classification atonic and hypertonic (spastic). "There is little or no evidence for atonic constipation." He describes the spastic type as a definite entity and cites *Buckstein's* grouping based on stasis proximal to some par-

ticular sphincter or in a definite segment of bowel. A very rational therapy is described.

CONGENITAL ANOMALIES

Kantor describes a logical procedure to assist in locating the blind end of the rectum in imperforate anus. After a colostomy has been functioning satisfactorily, a catheter on a catheter guide is passed through the colostomy stoma into the lower segment and after incision of the anal depression a finger is passed upward to palpate the end of the catheter.

Rhodes reports a case and discusses the method of caring for this condition.

A colostomy in an infant is less satisfactory than in older patients; even so in case of complete atresia it offers the infant a better chance for its life than blind exploration to locate the rectum if the blind end is much separated from the anus.

Kantor records his study of 2000 cases of anomalies of the colon. He classifies them as follows: Redundancy, Non-rotation, Hypodescent, Hyperdescent, Hypofixation and Hyperfixation. Unless obstruction occurs these should generally be treated conservatively. Symptomatic treatment is all that is usually required.

Gardner and Hart state that a knowledge of normal intestinal rotation is important to an understanding of the possible abnormalities. They report 2 cases of volvulus of the entire mesentery giving symptoms of duodenal obstruction and review 103 reported cases.

SECTION IX—*Book Reviews*

(This section is open to contributions from any medical reader, whether or not a member of the Editorial Council).

Medical Treatment of Gall Bladder Disease, by Martin E. Rehfuss, M. D., Clinical Professor of Medicine and Guy M. Nelson, M.D., Instructor of Medicine, both of Jefferson Medical College, Philadelphia, Octavo 467 pages, Illustrated. Published late in 1935 by W. B. Saunders Company, Philadelphia. Cloth $5.50 net.

NO type of book so appeals to the practitioner as does one concerned with *treatment*. In the book discussed, the Authors have presented *in extenso* those forms of management which they have found most useful in the care of patients affected with "gall bladder" disease. What they exhibit may not be wholly acceptable to other authorities in this kind of affection, but at least a definite plan of treatment is presented. In a field which has been so chaotic, such is a major achievement. However, the Authors have discussed much more than therapy. What perhaps, is of as great value, is that they have furnished excellent summaries of etiology, pathology, physiology and, though it may not be directly germane to the subject of treatment, they have gone deeply into methods and results of diagnostic procedure. Their own work—a very considerable contribution to our knowledge of liver, gall bladder and duct disease, etiology and pathology—and that of others, has been set forth in such detail as to comprise a veritable encyclopaedia upon the modern knowledge of the subject considered. Certainly, one who reads this book by Rehfuss and Nelson cannot fail, instinctively, to contrast it with texts—as those of Rolleston—which, for some thirty years, have been regarded as "standard." This contrast is, in all ways, educational, since this latest volume makes a valiant attempt to premise all therapy on sound facts, not clinical opinions by so-called "authorities" or compilations of more or less questionable data from many non-related sources.

Today's idea of basing treatment upon established facts cannot be commended too strongly; it may mean a less flowing style of manuscript, a book not capable of being read "in an evening," a shorter list of "remedies" and a feeling that there is much yet to learn about the subject, but it eliminates a vast deal of guessing, glibness and cocksureness, and confines management along paths which are well-trod and give promise of leading somewhere, even though that "somewhere" may be not a journey's end.

By chapters which include complete summaries of accepted knowledge of The Problem, Gall Bladder Anatomy, Clinical History, Methods of Examination, etc. (24 in all) the Authors pave the way for sections discussing management by diet, medicinal agents, duodenal tube "drainage," spa regime, surgery. Each chapter is a complete exposition of its topic and, what is more, to the reader, a definite, reasoned plan submitted in accordance with what the writers have found useful in day-by-day clinical and private practice. This sort of thing is what makes the volume invaluable to the general—and the special, too—practitioner; so invaluable that he cannot afford not to have the book right at hand for daily guidance. We venture to prophesy that not alone will the dietetic tables and prescriptions of Rehfuss and Nelson find their way into "patients' orders" of inumerable practitioners but that, as a result of the issuance of this book, more rational management of "gall bladder" disease will be observed, much to the distress of the manufacturers of the all-too-numerous nostrums which now flood the market as "specifics."

While one may disagree as to whether diets largely should be carbohydrate, so that the diseased "gall bladder" may experience physiologic rest, or preponderately fatty (excluding the denser meat fats) and thus stimulate emptying of the viscus, nevertheless, he will agree that the Authors' discussions and their dietetic lists furnish adequate guides for the selection of menus which prove sufficiently varied for the average patient. It would appear that when the "gall bladder" disease is acute or sub-acute, exhibition of diets which largely consist of carbohydrates will prove most helpful, whereas the patient who harbors a chronic affection will be benefited most by fat-containing diets which aid in preventing gall bladder retention. In each type of ailment, all authorities agree that the

minimum of cholesterin-containing or producing foods is demanded.

Endorsement of spa regimens, common to Continental physicians, suggests that the training of the Senior Author definitely has been influenced by the French clinicians. It is perhaps, unfortunate that physicians of the United States have failed to appreciate the advantages to "gall bladder" patients of the several excellent "Springs" here available. What may be the significance upon pathology of the biliary tract, of drinking medicated waters is open to question, but, amply, it has been demonstrated that, at the spas, the regulation of diet, exercise, rest and sleep, combined with changes of scene and freedom from the worries and responsibilities of business, home or society, distinctly are helpful to the "bilious" subject. Here and abroad, only the too-inclusive claims respecting the potency of the various waters, and the air of commercialism and semi-charletanism prevalent at spas have mitigated against the wide professional acceptance of resorts catering to balneo-therapy. It seems quite probable, though, that if the pitch of American business and social activity continues high, the day is not far distant when, under really honest and capable professional guidance, our spas and their regimens again will be called upon to take care of the ever-increasing army of "liverish" citizens. Perhaps Drs. Rehfuss and Nelson have sounded the warning note in their excellent treatise.

Very unfortunate, indeed, is it that a book of such eminent qualities as this should be so woefully mistitled.

It has taken full twenty years for investigators and clinicians to establish that "gall bladder" disease is but part of an extensive, often progressing, lesion involving common-duct, gall bladder, with its cystic duct, hepatic ducts, their ramifications so far as to include duct "capillaries" and the very substance of the liver itself. Even more to the point is it, that the Authors' tremendous and inclusive amount of investigative effort (particularly that of the Senior), all of which is exhibited in detail in their book, so very definitely proves that when the gall bladder is diseased, that affection is but *part* of lesions of similar kind, though they may vary in degree, of the other segments of the bile producing and excreting apparatus. This makes one truly astonished at the volume's limiting title. Further, as one reads this valuable work, certainly, he is impressed that the advocated treatment programs constitute far more than one is accustomed to call "medical."

Would it not be an indication of now-known pathology, physiology, chemistry, metabolism and nutrition, dietetics, physiotherapy and the use of medicinal agents, as well as a needed, constant warning against dangerous, outmoded, limited clinical thinking, were this important volume titled, "Non-Surgical Management of Biliary Tract Disease." The reviewer thinks so. He believes that, as anyone studies the altogether admirable plans of treatment detailed, the conviction most strongly grows that "gall bladder" and "medicine" constitute but small portions, respectively, of disease discussed and therapeutic effort applied. It is our hope that the first edition of this work very rapidly is sold so that, with the issuance of another edition, a title is given which correctly conveys what really is to be treated and broadens the conceptions of suggested therapeutic aids. Apart from this being just to the reputations, the investigative studies and the clinical experience of the Authors, such adjustment of title is called for, so that constantly there may be carried to our profession the knowledge that "gall bladder" disease is a mis-nomer. One's conception should include a set of clinical syndromes frequently, but not always, associated with disease or improper chemical or physiological function of the gall bladder. Unless, the clinician grasps this essential distinction, his horizon is limited with respect both existing and possible subsequent tissue-faults, in regards the histopathogenic meaning of complications and, perforce, intelligent exhibition of diets, drugs, exercise. Further, biliary tract pathology—frequently not significantly due to that present in the gall bladder—so markedly disturbs general systemic welfare and brings digestive lamentations from the oesophagus, stomach, duodenum and the bowels (we but mention the glycosuria associated with secondary pancreatic dysfunction that we may call attention to the many, long-lived "diabetics" in every community who uselessly take insulin and "special diets"!)—lamentations not silenced by cholecystectomy or by years of "duodenal tube drainage of the gall bladder," that the need for a view broader than that focused upon the too-often maligned or attacked gall bladder, has become imperative. Too few years since, removal of the "chronic appendix" was esteemed a panacea for a multitude of dyspepic discomforts and storms, most of which persisted or reappeared soon after appendicectomy. This book by Drs. Rehfuss and Nelson demonstrates emphatically why, with his eye on the gall bladder alone, when the surgeon performed cholecystectomy (or cholecystostomy; the storm still rages as to which is the better procedure; as routine operations, both are gambles) the internist later treated the "bilious dyspepsia"—the digestive disturbance which, in large part, from its beginning, depended upon biliary tract disease, not pathology or upsets in excretory, chemical or physiologic function of the gall bladder alone.

This book by Rehfuss and Nelson, though it be mistitled, follows the admirable modern trend of issuing authoritative monographs upon special topics, instead of printing huge volumes which rarely are more than out-dated compilations from the literature, made by one or a group of questionably qualified, so-called "authors." Just as the recently published monograph of Eusterman, Judd and their affilliates supplied our profession with worth-while discussions of ailments of the Stomach and the Duodenum, so this latest Saunders' effort aims at rational covering of the "gall bladder" (more accurately, biliary tract) field. Such plan of publishing appeals strongly to the reviewer. He feels that the day is past when, except in books of the "quiz-compend" type, physicians will load their shelves with expensive "systems" or thick, heavy, difficulty handled, single volumes, purporting to cover all subjects and oft, indeed, compiled (and all too often actually *written*) by medical, literary "hacks" or the young assistants of important, but alas, too busy for actual book-writing, clinicians. The trend towards the publishing, at fair prices, of single books, filled with down-to-date matter, actually submitted by men who are recognized authorities, we believe, means a revival of activity to the medical book-printers and a recreation of physicians' interest in book owning and

reading. But the books which are printed must be authoritative, must be well arranged as to text and illustrations and above all, must be sold at fair prices.

In issuing Drs. Rehfuss' and Nelson's book, the Saunders' Company has demonstrated what can be done along these lines. The volume is of size easily handled while being read, is bound substantially, has strong white paper which well takes a type-font restful to the eyes, is carefully indexed and yet, with all these advantages, is sold at a price which physicians can pay.

Frank Smithies.

SECTION XI—*Societies, Programs and Proceedings*

Program of the 39th Annual Session of the American Gastro-Enterological Association

MAY 4TH AND 5TH, 1936

ATLANTIC CITY, NEW JERSEY

MONDAY, MAY 4TH, 1936

MORNING SESSION, 9:30 A. M.

MEMORIAL ADDRESSES

Dr. John Bryant, Dr. Lafayette B. Mendel.

PRESIDENTIAL ADDRESS

Dr. Howard F. Shattuck, New York, New York.

"Hypoglycemia—A Clinical Survey of Four Hundred Cases Having This Common Finding." Dr. Lay Martin, Baltimore, Md.

"Thoracic Stomach and Diaphragmatic Hernia." Dr. Leon Bloch, Dr. A. M. Serby (by invitation), Dr. Samuel Salinger (by invitation), Chicago, Illinois.

"A Consideration of Some of the Newer Methods for the Treatment of Peptic Ulcer." Dr. Andrew B. Rivers, Rochester, Minn.

THE ALVAREZ LECTURE

Founded in 1929 by Dr. Frank Smithies, Chicago.

"The Digestive Tract in Anemia." Dr. George R. Minot, Boston, Mass.

Adjournment for Luncheon.

2:30 P. M.

"Miscellaneous Observations on Intubation of the Small Intestine." Dr. T. Grier Miller, Dr. W. Osler Abbott, Dr. Walter G. Karr (by invitation), Philadelphia, Penn.

"Regional Ileitis." Dr. A. A. Berg, New York, N. Y.

"The Components of Gastric Secretion." Dr. Franklin Hollander, New York, N. Y. (by invitation).

"Gastric Secretory Behavior in Chronic Gastritis." Dr. H. L. Bockus, Dr. J. F. Monaghan (by invitation), Dr. Karl Kornbloom (by invitation), Philadelphia, Penna., Dr. George R. Moffett (by invitation), Harrisburg, Penn.

EXECUTIVE SESSION

(For Fellows of the Association only).

ANNUAL DINNER, 7:30 P. M.

GUEST OF HONOR

Dr. William Mather Lewis, President Lafayette College, Easton, Penn.

"The Cultural Background of the Professional Man in Medicine."

TUESDAY, MAY 5TH, 1936

MORNING SESSION, 9:00 A. M.

"Further Experimental Studies on the Etiology of Ulcerative Colitis: The Possible Virus Factor." Dr. Moses Paulson, Baltimore, Md.

"The Diagnostic Significance of Anti-Dysentery Bacteriophage." Dr. T. T. Mackie, New York, N. Y.

"Symposium on the Pancreas."

Physiological Aspects: Dr. A. C. Ivy, Chicago, Ill.

Pathological Aspects: Dr. William G. MacCallum, Baltimore, Md.

Medical Aspects: Dr. Thomas R. Brown, Baltimore, Md.

Surgical Aspects: Dr. Daniel F. Jones, Boston, Mass.

"Report of Special Committee on Enzymes." Dr. A. H. Aaron, Chairman, Buffalo, N. Y.

Adjournment for Luncheon.

2:00 P. M.

"Cholesterol Metabolism in Jaundice." Dr. S. Allen Wilkinson, Boston, Mass.

"Biliary Stasis." Dr. Carl H. Greene, Dr. J. Russell Twiss, Brooklyn, N. Y.

"Chronic Hepatitis with Jaundice (Biliary Cirrhosis)." Dr. James F. Weir, Dr. Albert M. Snell, Rochester, Minn.

"The Prognosis of Acute Hepatic Insufficiency." Dr. Chester Jones, Boston, Mass.

"Macrocytic Anemia in Diseases of the Liver." Dr. David H. Rosenberg, Chicago, Illinois.

"Specific Food Sensitiveness." Dr. Walter Alvarez, Rochester, Minn.

(Asociación Mexicana de Gastro-enterologia)

AT Mexico City, Republic of Mexico, on July 17, 1935, there was organized the "Asociación Mexicana de Gastro-enterologia."

Dr. Abraham Ayala Gonzalez, Mexico City, was elected President.

The Association's main purposes, as set forth in its Articles of Incorporation and its Constitution are:

1. To bring together physicians specializing in this branch of medicine.
2. To encourage and to broaden the study of Gastro-enterology in Mexico.
3. To facilitate, in Mexico and abroad, interchange of specialized studies in this field of medicine.
4. To initiate and further research studies in Gastro-enterology.
5. To establish, publish and issue an official periodical for the Association, titled "The Mexican Review of Gastro-enterology."*

The official address of the organization is: "Asociacion Mexicana de Gastro-enterologia," Marsella No. 47, Mexico City. Communications for the present, should be addressed directly to Dr. Abraham Ayala Gonzalez, President.

*The periodical, nationally, is titled, "Revista de Gastro-enterologia." Volume I, No. 2, dated November-December, 1935, recently has been received. Editor.

SECTION XII—*"The Clinic"*

Gastro-Duodenal Hemorrhage of Unknown Origin: A Case Report

By

CHARLES D. ENFIELD, M.D.
LOUISVILLE, KENTUCKY

WE have long been familiar with the type of patient, whose first gastro-intestinal symptom is a massive hemorrhage; who was prior to the moment of bleeding able to eat anything without discomfort; who experienced no typical chemical discomfort; and who had in fact considered himself to be in excellent health until floored by the hemorrhage. These patients have frequently shown no abnormality whatever on X-ray examination and are, as a rule, put on ulcer management purely on the clinical assumption that the bleeding must have come from an ulcer. Not infrequently these patients go on to complete recovery, never have ulcer symptoms, and never have another hemorrhage; or they may have repeated hemorrhages without ulcer symptoms.

We have also long been familiar with the type of individual, who, under nervous strain, develops typical ulcer symptoms with hyperacidity, but who fails on careful X-ray examination to show any ulcer deformity. These patients many of us have classed as instances of gastro-duodenal expression of apprehension, nervous fatigue and worry, and they are usually relieved by an improvement in their business or domestic situation, a trip abroad, or in fact anything that relieves the nervous tension. They are generally high strung, energetic and of greater than average intelligence. Many of them are doctors and I am sure all radiologists have had the experience of having a friend in the profession present himself with a self-made diagnosis of ulcer or occasionally gastric cancer only to find on repeated examination no evidence of any lesion whatever.

Submitted December 9, 1935.

This case history suggests that perhaps these two groups—the one with hemorrhage but with no symptoms and no duodenal deformity and the other with typical ulcer symptoms but without hemorrhage and likewise no duodenal deformity, may occasionally combine into an undoubtedly much smaller group, which may evidence not only a typical clinical picture plus hemorrhage, but also a typical Roentgen appearance.

It has appeared to the careful and well trained radiologist that the diagnosis of duodenal ulcer with almost mathematical certainty ought to be chiefly a matter of expending sufficient time, effort and skill in demonstrating the niche. This procedure is more difficult in certain types of patients, easier in others. For many years a small percentage, perhaps up to thirty-five per cent, of niches have been demonstrated without special apparatus or technique. The demonstration of a niche can be greatly facilitated by the use of various forms of special apparatus, mostly hinging about compression devices, and with their wider use the percentage of niches demonstrated has increased materially. It is felt by the majority of radiologists that where a niche can be demonstrated, there should be no practical doubt as to the existence of an ulcer, and, conversely, it should be possible to demonstrate a niche, where an ulcer exists, in a very high percentage of cases.

CASE REPORT

The patient, a white, male physician, whose case I wish to report, had occasional attacks of abdominal distress as a child, more severe than the ordinary attacks of colic. As a young man, these attacks occurred at intervals of a year and a half or two years, sometimes required morphine, and were invariably relieved by twenty-four hour

abstention from food, and were usually accompanied by vomiting.

In 1922, at the age of thirty-six, he began to have definite, typical ulcer symptoms with attacks in the spring and occasionally in the fall, lasting three or four weeks. He was relieved by almost anything *remotely* approaching Sippy management. He was likewise relieved by a change in environment, a rest, a trip, sometimes by belladonna. During the nine years in which the symptoms persisted he worked out a thoroughly unorthodox method of management, which, however, left him in a fair degree of comfort and able to attend to his work practically without interruption. He was profoundly aware that certain foods, such as pork, all members of the bean family, highly seasoned sauces, pickled or smoked meats or fish were apt to disturb him acutely. He found he was almost never disturbed by lobster, shrimps, and many other articles of diet commonly interdicted for ulcer patients. His lesion seemed to have no tendency to perforate or to bleed and for several years he was firmly convinced that a reasonably intelligent individual could get along quite comfortably with a duodenal ulcer, if he humored it a little.

During these years the patient was examined by several radiologists, more than one of national repute, and in each instance a typical duodenal deformity was demonstrated with ease and constancy. The last two or three examinations showed a definite niche or ulcer crater penetrating posteriorly in the direction of the pancreas. Since this niche was demonstrated on not one but on a considerable series of films and not at one examination but at least on three occasions separated by several months, there was no doubt in the mind of the patient or of his medical advisors that he did in fact have a chronic penetrating duodenal ulcer.

During this period several gastric analyses were made, all of which showed abnormally high acids and most of which showed chemical blood.

About nine years after the onset of definite symptoms, the patient suffered without warning a massive hemorrhage, which almost proved fatal, and for which an emergency laparotomy was performed. Transfusions were given before and after operation. Neither the surgeon nor the internist chiefly concerned were at all enthusiastic about operating during gastric or duodenal hemorrhage but the failure of medical measures to control the hemorrhage with a hemoglobin estimated at twenty-three per cent of normal convinced both of the desirability of operating as an emergency procedure. No attempt was made to do anything other than find and close the bleeding point, and there appears to have been some question as to whether this was successfully accomplished since the patient bled again five days later.

Symptoms recurred within a few weeks and were at first confined to typical chemical discomfort relieved by alkalies. However, other hemorrhages ensued and, as there appeared to be some tendency to obstruction or at least some delay in emptying the stomach, a gastro-enterostomy was performed by another surgeon.

Symptoms still persisted and hemorrhages continued. Approximately two years after the first hemorrhage and emergency surgery, and approximately a year after the gastro-enterostomy, the patient went to the operating table a third time and the stomach below the gastro-enterostomy was removed together with the first part of the duodenum. The gross specimen was found to show no ulcer, no scars, and in fact to present the appearance of perfectly normal gastric and duodenal mucosa. The duodenum was not adherent to the pancreas. The specimen was submitted to a competent pathologist, who reported both the gross and microscopic appearance normal, and he was not more successful than the surgeon had been in finding evidence of ulcer, old or recent.

The complete failure to find any pathological explanation of the perfectly typical ulcer symptoms, extending over a period of eleven years, and accompanied by typical X-ray findings on numerous occasions, was a shock in more ways than one. The only possible explanation of the X-ray appearance in the light of the negative pathological findings seems to be that it was caused entirely by spasm, perhaps purely of functional nervous origin, or possibly due to superficial mucosal ulcerations, which healed promptly and without scarring. Naturally the X-ray examinations were made at times when symptoms were unusually pressing, and certainly the combination of circumstances here recorded must be so rare as not to discredit to any serious extent the accuracy of X-ray diagnosis of duodenal lesions. It should perhaps be emphasized that the X-ray examinations referred to were performed without special compression devices and in fact prior to the invention of most such devices now in use. There is in the writer's opinion little doubt that the compression device itself may under certain circumstances cause, in the normal duodenal bulb, an appearance closely simulating an ulcer crater.

Treatment of Chronic Ulcerative Colitis

Report On Five Cases

By

EMOR L. CARTWRIGHT, M.D.
FORT WAYNE, INDIANA

THIS devastating disease is assuming more serious proportions each year. While great strides in its treatment, have been made by Bargen and others, it is still true that the acute fulminating type may terminate fatally or, in the event of recovery, leave the patient with a permanently crippled colon. As stated by Bargen, the patient with chronic ulcerative colitis must be considered in the same light as a patient with pulmonary tuberculosis. The disease may be arrested, but there is the ever-present threat of recurrence.

Any remedy which aids in the control of this malady is worthy of being brought to the attention of the medical profession. We have found such a remedy in Alpha Naphco Jelly and liquid. While we believe that the Bargen serum is needed in the acute fulminating type, Alpha Naphco is an excellent remedy after the case has been brought under control. This remedy

Submitted December 9, 1935.

alone, however, will suffice to clear up cases of the ambulant type.

The following five case histories are reported from a clinical standpoint only. The clinical diagnosis in all was chronic ulcerative colitis. The progress of each case was followed through the proctoscope. In three of the cases a number of the usual remedies had been used by the referring physicians before I finally saw the patients.

CASE REPORTS

F. M., Male, 25 years old, January 29, 1935.

I saw this young man first in February, 1932, when he was bedfast with a fulminating type of chronic ulcerative colitis. At this time the Bargen serum was used which brought about a remission in the disease. Since that time he has had several recurrences. The last one occurred January 29, 1935, and he was put on Alpha Naphco liquid 25 gtts in hot water after meals and Alpha Naphco capsules four before each meal. This was the only treatment given and it very promptly brought about a remission. He was dismissed February 18, 1935.

A. I., Female, 50 years old, November 10, 1935.

History: Since June, 1933, she has been passing blood and mucus as soon as she gets up in the morning, having several such movements before noon. She usually has a bowel movement about noon. She has had no pain and no cramps. She has lost no weight, but she is somewhat weaker.

She had malaria thirty years ago here in Allen County, Indiana, but has had no other serious illness.

The referring physician stated that he had given her hypodermatic injections of emetine and a course of carbarsone by mouth.

Examination: Palpation of the abdomen revealed no tenderness and no tumor masses. The anal margin was negative. The anal canal was inflamed and bled easily. Proctoscopy revealed a boggy mucosa with minute ulcerations. A ten-inch sigmoidoscope was passed, and minute ulcerations were found in the sigmoid mucosa. The mucosa was spotted with blood flakes.

Treatment began November 10, 1934. She was put on Alpha Naphco capsules and liquid. She took two capsules before each meal and at bedtime, and 15 drops of the liquid every hour in hot water, ten doses daily. This was the only treatment she received and it was continued until she was well.

November 21st. Proctoscopy revealed blood and mucus in the rectum.

November 22nd. A warm stool was examined at St. Joseph's Hospital, and no amebae were found. The stool contained pus and blood.

November 24th. The capsules were increased to four, four times daily and the liquid to 25 drops every hour.

November 28th. Proctoscopy showed the mucosa healing. It was not so boggy and the bleeding was less.

December 5th. Proctoscopy showed the mucosa healing.

December 13th. Proctoscopy showed the mucosa to be practically normal and she was dismissed.

To date, (September 20, 1935), there has been no recurrence.

D. C. S., Male, 27 years old, April 12, 1935.

History: Patient had consulted the referring physician one year previous to the time I saw him. Various irrigating solutions had been used, and numerous intestinal antiseptics had been administered without any help. Bleeding from the rectum continued. He would pass blood immediately after getting up in the morning, have a bowel movement, and then pass more blood.

His previous history was negative. He has spent his entire life in Indiana excepting three years spent in Boston.

Examination: Inspection and palpation of the perianal region were negative. The anal canal was free from any pathology.

Proctoscopy showed beginning hemorrhoids in the lower rectum. The mucosa was boggy and bled easily. There were multiple bleeding areas with tiny ulcerations in the rectum and in the sigmoid. The picture was typical of chronic ulcerative colitis.

Treatment: He was put on a bland diet. On April 17, 1935, he was started on Alpha Naphco liquid 15 gtts every hour in hot water and Alpha Naphco capsules, two before each meal.

April 22nd. Proctoscopy showed the mucosa to be looking better. Patient stated that he has not passed any blood for two days.

May 1st. He had noticed recurrence of blood, so the dosage of the Alpha Naphco liquid was doubled.

May 8th. He was passing no blood and he continued to improve until May 24th when sigmoidoscopy showed a recurrence of the disease all along, with punctate ulcers. Alpha Naphco liquid and capsules were continued.

May 27th. He was much improved. He was told to discontinue raw cow's milk and to use instead evaporated milk.

June 3rd. The mucosa had healed, and he was passing no blood. Dismissed.

To date, October 14, 1935, there has been no recurrence.

S. G., Female, 62 years old, September 24, 1935.

History: For the past two months she has had rectal bleeding. Passes blood the first thing in the morning and then some at stool a little later. Previous to this she was well excepting that she would tire easily. A year ago a doctor told her she was anemic. She has always been constipated.

Examination: Abdomen negative. Digital examination of the anus is negative. Anoscopy shows bloody mucus in ampulla. Proctoscopy shows a boggy mucosa with ulcerations. Mucosa bleeds easily when touched. No tumor found.

Treatment: She was started out on brewers yeast, bismuth subnitrate, mineral oil, and cod liver oil.

October 8th. All medicine was discontinued and she was put on Alpha Naphco liquid 20 gtts in hot water every hour. She could not take capsules saying she positively could not swallow them. As she was constipated, sodium phosphate was prescribed.

October 22nd. Cod liver oil was again started.

October 29th. She was feeling much better. Passing less blood.

November 12th. (No Alpha Naphco on hand). She was put on Karicin which she took for about four weeks. It was discontinued later.

December 17th. She was started on Alpha Naphco liquid 30 gtts in hot water every hour, ten doses daily. This medication was continued during the winter and in February, 1935, she was all right.

In June, 1935, she had a recurrence of the rectal bleeding. She was put on reduced iron tablets. Alpha Naphco liquid was started again and was continued during the summer.

August 7th. Her teeth were X-rayed and found to be normal.

September 4th. Proctoscopy showed the mucosa to be normal and she was dismissed.

October 31st. An X-ray following a barium enema was negative excepting for the evidences of a healed colitis. On account of her age the Alpha Naphco liquid will be given intermittently with the hope that it will prevent any recurrence.

C. S. A., Male, 28 years old, April 17, 1935.

History: In November, 1934, he noticed a little blood after a bowel movement. He has had no pain but an uncomfortable feeling in the abdomen. He has lost neither weight nor strength.

His home was in Mississippi until July, 1929, when he moved North. He had the usual childhood diseases, nothing else, and no operations. He never had malaria nor any dysentery. The referring physician states that he has used anti-amebic treatment (emetine) and also some of the arsenic preparations. Rectal irrigations were used over a long period.

Examination: Abdomen negative. Inspection and palpation of the perianal region and anus were negative. Proctoscopy showed an edematous and redundant mucosa, containing many tiny ulcerations. The rectum contained some bloody mucus. Sigmoidoscopy at six inches showed a normal mucosa.

On April 20, 1935, warm stage examination showed nothing but red cells.

Treatment: He was started on Alpha Naphco liquid 15 gtts every hour in hot water, ten doses daily, and Alpha Naphco capsules two before each meal.

May 1st. There has been no improvement.

May 4th. Patient states that he is feeling a little better. Mucosa looks a little better.

May 13th. Not so good. There was free blood in the rectum.

May 15th. Mucosa a little better.

May 22nd. A little better.

May 27th. No improvement. To discontinue pasteurized milk.

May 31st. Increase Alpha Naphco capsules to three, four times a day.

June 20th. Has not passed any blood for two weeks.

June 27th. Some blood flakes in the rectum.

July 2nd. More blood in the rectum, but he is feeling fine. He is leaving the city for three weeks on a vacation. I gave him enough Alpha Naphco liquid and capsules to last during this period.

July 23rd. Returned from his vacation feeling fine.

July 30th. Mucosa is boggy but he passes no blood.

August 6th. Mucosa looks fine.

August 13th. Proctoscopy shows everything to be normal. Dismissed.

The experiences of others would indicate that respiratory infections are the greatest contributing cause of recurrences in chronic ulcerative colitis. With this in mind patients should be very careful not to contract colds. Their resistance should be kept up to par by eating abundantly of wholesome foods, and taking cod liver oil, during the winter months especially. While diet does not apparently play a very great role in the treatment of the disease, still I think it is wise to refrain from asking a sick colon to handle the residue from the leafy green vegetables.

F. R. BERNHARDT.

What is the Significance of the Invading of Stomach Contents into the Bile Ducts Following Anastomosis Especially Cholecocho-duodenostomies? Archiv. f. Klin. Chirur., Vol. 180, Sept. 21, 1934.

An exhaustive report is given of 22 cases where anastomosis was performed between the bile ducts and the adjacent organs with careful follow-up histories, roentgen examination included. This surgical procedure being recently undertaken more frequently, evolves the so-important question of ascending infection from the stomach or bowels. The answer is not uniformly affirmative. The Author collected, however, a certain number of cases where such infection has not occurred. It must be cited, however, that passing of duodenal content into the bile ducts is not always harmless and often is followed by damaging effects upon the mucosa of the bile ducts. The prevalence of acids are often playing a decisive role in that for instance in cases of decreased HCl secretion the administration of HCl and pepsin may counteract ascending infections with comparative certainty.

Entrance of the barium meal into the bile ducts was visualized in one case where the hepaticus was anastomosed to the stomach. In three cases of cholecystogastrostomies it penetrated once, in six cases of cholecystoduodenostomies it invaded twice and in 15 cases of choledocho-duodenostomies it gained access eight times into the bile ducts. In the latter cases concommitent attacks of cholangitic processes were observed. Possibly a dilatation of the smallest ducts was responsible for such complications. It is noteworthy that where barium did not invade the bile ducts cholangitis also was absent. Untoward results are often due to faulty technic such as too narrow anastomosis. In these cases a stenosis may be responsible for the complaints which are similar to those of common duct stones. Sometimes the retroduodenal portion of the common duct shows stasis and thus may give rise to secondary ascending infections. To overcome this, it is advisable to perform the anastomosis at the lowest point of the choledochus, an advantage resulting in diminished traction upon the duodenum.

Such operations ought to be considered as major surgical measures. Although often life saving they are not always harmless. Consequently indications must be taken very judiciously. Complete stenosis of the common duct with a functionless gall bladder is one of such indications. Other processes obstructing the flow of bile within the papilla also belong here. Another large group consists of lesions involving the pancreas, *i.c.* induration of the head, tumors, widespread adhesions obstructing thus a satisfactory flow of bile, etc. In such instances the choledochoduodenostomies are especially the operation of choice. Incidents are mentioned where the post-operative course remained satisfactory 18 years after such operation. In most of cases complete obliteration of the common duct was found. The gall bladder had been removed previously because of stones. Anastomosis was performed between the duodenum and the common duct resulting in stormy post-operative courses, manifested by severe cholangitis. In these cases the barium swiftly invaded the smaller bile ducts and almost invariably a shadow was seen in the retro-duodenal portion of the common duct.

Choledocho-duodenostomies should be performed in the appropriate cases with a most meticulous technic. Because of the possible complications, however, the indications for such procedures must be cautiously weighed.

H. KALK.

Hereditary Factors in Lesions of the Gastro-intestinal Canal. Deut. Med. Woch., No. 39, Sept. 20, 1934.

A short and interesting survey is given about inheriting anomalies, constitutional types and finally diseases of

the gastro-intestinal tract. To ulcer disease is devoted a great deal of attention. "Ulcer Families" are described where the occurrence of ulcers could be traced to the second or third generation with almost identical complications such as hemorrhage and perforation. The contention that such stomachs are all afflicted with a lowered resistance, a so-called "Minderwertigkeit" is still a muted question. Malignancies of the stomach may also be inherited revealing sometimes identical predilection of invaded areas. Gastritis also may be found as revealing hereditary tendencies, manifested by achylias and pernicious anemias. The haemolytic jaundice described by the French as Familial Cholemias and by the Germans as Constitutional Hyper-bilirubinemia is well known. With regard to Cholecystopathias one can say that the stronger the hereditary tendency the sooner we may expect stone formation, inflammations or other derangements of the bile ducts.

BODMAN, FRANK, M.D.

The Psychologic Background of Colitis. Amer. Jour. Med. Sc., pp. 535, Oct., 1935.

The writer states that the bacterial cause of ulcerative colitis has not been convincingly proven and it has been overlooked that it constitutes a terminal stage in a colon which has been the seat of disorganizing dysfunction. Ulcerative colitis is incurable as gross organic changes have taken place in the mucosa of the bowel, in the myocardium and in the elastic tissue of the arteries.

Prevention of these terminal stages can be attained if the functional disorder is recognized in good time and as partly an expression of an emotional state.

The Author predicates that colonic dysfunction begins during breastfed infancy. The baby upon defecation experiences discomfort, cries for his mother or nurse; a call for help or attention and another conditioned reflex in infancy may be established by the emptying of the bowel when the child is frightened — by being handled by strangers or examined by physicians in a children's ward.

The next psychologic factor in the development of bowel function is that invoked in the training of the infant to a regular reflex. This is the first demand made by society—through the mother or nurse on the infant. If the response to the reflex is prompt and satisfactory it receives encouragement —that if it fails to respond displeasure may be exhibited by its guardian. It has discovered a new channel for exercising power.

Twelve cases are described which illustrate the various stages and degrees of functional and organic disorders of the colon. The family and personal histories of these cases are meticulously dealt with and the psychogenic factors emphasized both in the development and management of the disorder.

ROSEDALE, R. S.

Jejunal Diverticulosis. S. G. and O., Vol. 61, No. 2, pp. 223-228, Aug., 1935.

Multiple jejunal diverticulosis is a rare condition; the Author has been able to find 71 recorded cases to date. Jejunal diverticula are classified as congenital, or acquired. The congenital diverticula are made up of all the layers of the intestinal wall, while the acquired ones contain only a fraction of the layers of the intestinal wall.

The etiology of these diverticula is obscure. Increased intra-intestinal tension, embryologic incoordination, and weakness of the intestinal wall at the point of entry of the vessels are probably important factors in their formation. Butler has concluded from some experimental work that sclreosis of the terminal branches of the superior mesenteric artery and the resultant formation of "traction pockets" is also an important etiological factor in the formation of these diverticula.

Complications of jejunal diverticulosis do not occur frequently. They may contain enteroliths and cause partial intestinal obstruction, or they may become inflamed and cause vague abdominal pain.

The Author reports three cases in detail. Seven figures and a bibliography accompany the article.

Nelson M. Percy, Chicago.

BLOOMFIELD, ARTHUR L., M.D.

The Mechanism of Decrease of Gastric Secretion With Advancing Years. Amer. Jour. Med. Sc., p. 325, Sept., 1935.

Bloomfield and Keefer, in 1928, were the first to demonstrate the steady drop in acidity which takes place with advancing years. Polland and Bloomfield confirmed this finding through histamin tests on essentially normal people. Vanzant and her colleagues showed that men have a more highly acid gastric juice than women.

This work established:

1. There is a marked fall in the average gastric acidity of men with advancing years and the curve is a straight line.

2. The average gastric acidity of young women is distinctly lower than that of young men, but the fall with advancing years is very slight.

3. The average volume of secretion both men and of women falls markedly with advancing years and the curve is a straight line.

It was found that there was not a gradual fall in all people because even in the older age periods a number of individuals are found who preserve a maximal secretion.

The rapidly increasing incidence of anacidity with advancing years also seems out of accord with gradual drop in secretion of the whole population.

The writer says it was very difficult to accomplish followup studies over a period of 5 or more years, therefore, they had only 6 cases so examined. Many observations showed the amount of variation by tests at brief intervals to be slight. Rather slight differences in secretion volume and acidity were revealed in these cases though there was a lessening tendency. One must look elsewhere then, for the explanation of the general fact that gastric secretion decreases with advancing years. The answer lies in certain cases in which there is a very rapid deterioration of secretion. The Author cites 2 case abstracts of instances of this sort. One was the case of a 33 year old teamster with a penetrating type of lesser curvature gastric ulcer in 1927. His acidity was normal—he was re-examined in 1934 and no free HCl was found nor was the ulcer demonstrated by Roentgen ray. He had taken alcohol freely and returned with anorexia and had vomited for a year.

The second case was one of a penetrating ulcer with pyloric obstruction first seen in 1929. The patient was 57 years old. Histamine test showed free HCl 88—, total 98, height volume period 41 c.c. The ulcer was excised and gastroenterostomy was done. It showed a benign gastric ulcer. Histamine test, September 9, 1933, showed free HCl 0 and total 12; volume 17 c.c.

Discussion: The observations show there is no uniform steady decline of gastric secretion in all people with advancing years. The level of secretion remains essentially unchanged; there may be a slight increase or a rapid failure may occur and lead to anacidity.

NUTRITION

BAUMGARTNER, L.

Pituitary Basophilism and Hypertension. Yale Jour of Biology and Medicine, Vol. 7, p. 327, 1935.

Since Cushing's description of the clinical phenomena associated with basophilic adenoma of the pituitary, another approach to the study of the relation of the pituitary to clinical hypertensive disease has offered itself. Baumgartner selected 13 cases of hypertension in young individuals in whom arteriosclerotic and nephritic complications were minimal, and no other complicating disease was present. Detailed clinical study including blood chemistry, X-rays of sella and skeleton, visual field determinations and basal metabolism, was made, and the results compared with the data for the 23 cases of pituitary basophilism now in the litera-

ture. The features characteristic of pituitary basophilism occurred in relatively few of the hypertensives, but the method of selection would eliminate those with advanced signs of basophilism.

(a) Obesity occurred in the majority and the typical distribution of fat to trunk and face with marked sparing of the extremities was recognized in 4 of the 13. In 5 cases the sudden increase in weight comparable with Cushing's description had occurred.

(b) Skin and hirsutism. In none of the hypertensives did the characteristic purplish striae occur. Polytrichosis was noted in 3 of the 8 women.

(c) Sexual dystrophies did not occur, except for menstrual irregularities in 2 women.

(d) Osteoporosis was lacking although it was a decided feature in some cases of basophilic adenoma.

(e) Erythrocytosis with counts exceeding 5,000,000 occurred in 8 of the 13 cases.

(f) Pathologic examination in 2 hypertensives revealed a small basophilic adenoma of the anterior lobe, associated with infiltrations of the posterior lobe with basophilic cells in one case and a normal gland in the other.

SPIES, TOM D.

The Medical Treatment of Early Pellagra. J. A. M. A., 105:1028, Sept. 28, 1935.

The two main theories of the cause of pellagra are: First, that pellagra is caused by a bacterium. The second theory is that it is caused by the lack of a specific chemical substance present in food. Neither of these theories has experimental proof.

The mortality rate in pellagra is high. The treatment of the moderately severe case of pellagra should be generally known. The diet should be well balanced and contain 4000 calories. The patient should have adequate rest. In addition good brewer's yeast, wheat germ or liver extract should be given in large doses. Any of these agents are best given in doses of from 10 to 20 grams in a glass of iced milk or iced eggnog every three or four hours for a total of 75 to 100 grams daily. Parenteral injections of liver extract are very effective coupled with brewer's yeast or wheat germ given by mouth. The patient should be watched and guarded against relapses.

DRAKE, E. H., HAWKES, R. S., AND WARREN, MORTIMER.

An Epidemic of Trichinosis in Maine. J. A. M. A., 105:1340, Oct. 26, 1935.

The Authors discuss the first recorded epidemic of trichinosis in Maine and possibly the largest epidemic to be reported in the United States. Infection resulted from the eating of improperly cooked homemade pork sausages. The infected meat and the striated muscles of two fatal cases showed the trichinellae. Of seventy-one individuals known to have eaten the sausage, fifty-six revealed signs of infection. Twenty-six persons ill with probable trichinosis were given skin tests, twenty-four of these were positive. The technique of the intradermal test for trichinosis is discussed.

RALLI, ELAINE P., AND WATERHOUSE, ALICE.

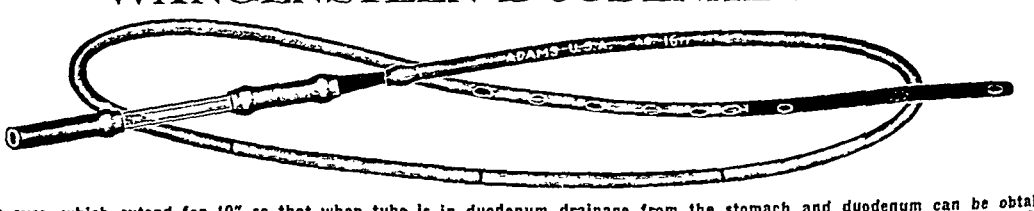
Studies on the Effect of the Administration of Carotene and Vitamin A in Patients with Diabetes Mellitus.
II. The Effect of a Cod Liver Oil Concentrate on the Blood Carotene and Cholesterol.
The Diabetic Clinics of the Third (New York University) Medical Division, Bellevue Hospital, and the Department of Medicine, University and Bellevue Hospital Medical College, New York University. Jour. of The Amer. Diet. Assoc., pp. 110-114.

A previous study showed that when a group of diabetic and non-diabetic patients were fed carotene that there was a greater increase in the blood carotene in the diabetic patient than in that of the non-diabetic. Because of this fact a study was made on the effect of a cod liver oil concentrate on the blood carotene and cholesterol in twenty-seven diabetic patients. The ages of these patients varied from 22 to 68 years; 14 of which were over 45 years of age. Six of these fourteen had a severe case of diabetes and eight mild diabetes. Of the cases under 45 years of age, ten were severe diabetic and three mild. After a controlled period during which time observations were made on blood carotene and cholesterol, the patients were given cod liver oil in the form of a concentrate. Fasting samples of blood were taken at intervals and blood carotene and cholesterol were determined from these samples.

The results of this experiment shows that:

The blood carotene increased in seven cases, fell in seven, and showed no change in thirteen cases.

An increase in blood cholesterol was associated with an increase in blood carotene in twelve patients.



In fourteen cases the blood cholesterol changes were in the same direction as the blood carotene changes.

There seems to be no constant relationship between duration or severity of diabetes and the height of the blood carotene. The reaction of the patient to the concentrate was practically the same in the various groups. There were no complaints attributed to the high blood carotene.

These results indicate that the effect of the concentrate on the blood carotene is much less than the effect of carotene in oil. It is the opinion of the writers, that since there is a definite increase in blood carotene in diabetic patients following the administration of carotene *per se*, it might be wiser to use Vitamin A as such in these patients until the clinical significance of an increase in blood carotene has been established.

KIRKLIN, B. R., AND BLAKE, THOMAS W.

Cholecystic Disease. A Comparison of the Clinical With the Cholecystographic Data Concerning 500 Patients Not Operated On. J. A. M. A., 105:1416, Nov. 2, 1935.

Cholecystography checked by subsequent surgery and pathologic examination has been proven to be a reliable test. There has been some doubt expressed regarding the reliability of cholecystography in non-operated cases.

A series of five hundred such patients examined clinically and cholecystographically but not operated on is here reviewed. The results of this study showed agreement between the clinical impression and cholecystographic findings in 90.8 per cent of these cases.

The results of this study would tend to prove that even in non-operated cases cholecystography is both useful and reliable. Cholecystography should be employed as an aid to the clinical examination. The two examinations can be employed profitably together.

THERAPEUTICS

CLERF, L. H.

Foreign Bodies in the Stomach Removed by Peroral Endoscopy. S. G. and O., Vol. 61, No. 2, pp. 210-213, Aug., 1935.

The Author reports a series of 849 cases of radio-opaque foreign bodies in the stomach and intestinal tract admitted to the Bronchoscopic Clinic of the Jefferson Hospital during a 10 year period ending in January, 1934. Of those, 818 passed spontaneously, 12 were removed by laparotomy, one by peranal endoscopy, and 18 were removed from the stomach by peroral gastroscopy. Among the objects which passed spontaneously were open safety pins, common pins, and a variety of sharp, pointed, and irregular foreign bodies. The Author, aided by a roentgenologist familiar with the technical phase of double plane roentgenoscopy, removed twelve foreign bodies by peroral gastroscopy. He recommends that method when removal is decided upon. In questionable cases the opinion of a competent roentgenologist should be secured to determine if the object can leave the stomach, and also if it will be able to traverse the angulations of the intestinal canal, particularly the duodenojejunal junction..

WEIR, JAMES F., AND SNELL, ALBERT M.

Symptoms That Persist After Cholecystectomy, Their Nature and Probable Significance. J. A. M. A., 105:1093, Oct. 5, 1935.

Cholecystectomy well performed on proper indications is an extraordinarily successful procedure. The patients who are not cured by cholecystectomy present a very difficult problem. Errors in diagnosis, poor selection of cases, residues of cholecystic disease, cholangeitis, hepatitis, and pancreatitis, stricture formation in the extrahepatic bile passages and post operative colic constitute the basis for poor results.

Careful diagnosis of the presence of gall bladder disease is important. Careful history, physical examination and cholecystography is stressed in making an exact diagnosis. Residual cholangeitis, pancreatitis and hepatitis, in some cases at least, account for poor results after cholecystectomy.

Stricture of the common bile duct after cholecystectomy is a rare cause of complaint.

Colic after cholecystectomy may be explained by stone in the common duct, stricture formation, residual pancreatitis, cholangeitis or hepatitis and in a few cases a spasm of the sphincter of Oddi with transient "physiologic" obstruction.

Francis D. Murphy, Milwaukee.

Dr. Raymond Leaves Rockefeller Institute To Head Searle Research

DR. ALBERT L. RAYMOND

ANNOUNCEMENT

Announcement has just been made by G. D. Searle & Co., Chicago, of the appointment of Dr. Albert L. Raymond as Director of their Research Laboratories.

To take this Searle appointment, Dr. Raymond resigns from the Rockefeller Institute of Medical Research, with which he has been connected for the past nine years, the last seven of which he was an associate of Dr. Levene.

For two years he was National Research fellow, working on problems connected with the biological mechanism of carbohydrate degradation.

Dr. Raymond is a Californian and gained his Ph.D. at the California Institute of Technology, Pasadena, in 1925. Afterwards he spent three years part-time teaching at California Institute of Technology and at the University of California.

He is a member of the American Chemical Society and the American Society of Biological Chemists.

Says Dr. Raymond:
"I know of no field offering greater facilities for the practical application of biochemical research than the laboratory of a pharmaceutical house Here we come in first hand contact with the problems of that working scientist, the practicing physician, and this is a great incentive to provide him with better chemical instruments with which to fight disease." (Adv.)

HOLMES, WM. H.

Medical Treatment of Amoebic Infections of the Liver. S. G. and O., 61:521-522, Oct., 1935.

The hepatic complications of intestinal amoebiasis include acute hepatitis and abscess. The treatment of the former is entirely medical and of the latter, abscess, is almost always surgical. The Author offers good reasons why this should also, in most instances, be treated medically. An amoebic abscess is quite different from a pyogenic abscess in that it results from the lytic action of ferments liberated by amoebae, that it is composed of liquefied liver tissue and red blood cells in various stages of disintegration, and that it does not contain cells of leucocytic origin in uncomplicated cases. The inadequacy of drainage is due in part to the fact that the amoebae are present in greatest numbers in the wall of the cavity and continue enlarging the size of the abscess. Aspiration if not unsuccessful may frequently cause dissemination, and open operation has a rather high mortality rate. Further, contrary to the usual view these abscesses are often multiple increasing the difficulties of either type of surgical drainage. Two patients treated by the Author as well as some reported by others were cured by medical treatment alone. He believes that surgical treatment should be reserved for cases complicated by secondary bacterial infections and for other complications, such as rupture of the abscess into the pleural or peritoneal cavities.

Surgical Treatment of Redundant Colon, in Particular the Precedure in one Stage, with Exteriorized End-to-end Closure. (Traitement Chirurgical du Dolichocolon, en Particulier Dans le Procedure en un Temps, Avec Suture Termino-Terminale Exteriorisee). Jour. de Chir., No. 2, pp. 188-201, Aug., 1935.

In this article the Authors give a general review of the subject of redundant colon, the different operative procedures already made use of, and describe their own technique which they have employed since 1931 in the treatment of five patients with five cures.

Constipation, painful crises, aërocolon, and volvulus, are the indication for operation. However, operative precedure need scarcely be employed in the treatment of constipation as an isolated symptom. The attacks of abdominal pain and aërocolon have the same causes which are especially of mechanical origin, thus by this fact rendering useful surgical intervention. These causes are (1) chronic volvulus and (2) kinking of the intestine; when the patient presents only attacks of pain without meteorism medical therapeutics suffices, in general, to either alleviate or to cure the condition for the lesions of a colitis suffice to explain the symptoms; but when the painful crises are accompanied by colicky distension, the treatment is more delicate.

If the symptoms persist for a long time it may be an indication for resection of the long (redundant) loop in order to remedy the possible twisting or kinking of the loop.

In the cases of intestinal obstruction the resection will be practised either during or after the attack, acording to the case.

For acute volvulus it is possible, by means of the present technique of the Authors, to resect the twisted loop if it is not sphacelated. When the operative procedure is limited to an untwisting of the loop it will be indicated, after the attack, to resect it in order to prevent a recurrence.

The Authors mention the operative procedures already utilized: resection of the rectal valves; dilatation of the anus; section of the first and second lumbar ramicommunicantes; ablation of

. . . of distinct service in digestive diseases

IN all forms of dyspepsia other than those arising from gastric ulcer or cancer, Vichy Celestins is of distinct service. Being easily assimilated, the water promotes gastric secretion and tends to normalize the function of the gastric glandular apparatus. In gastric neuroses and the milder forms of organic disease of the stomach, the stomach is soon physiologically improved, digestion accelerated, fermentation neutralized, and pain and nausea alleviated.

Vichy Celestins is the property of the French Republic, under whose supervision the water is bottled. The medical profession and all consumers are protected by a guarantee of the French Government as to the water's authenticity and purity.

The Tilden Company has used the name since 1924 and put up the formula, approved by authorities. It is intended that physicians shall get true DANISH OINTMENT when they write prescriptions for it since this is a most thoroughly effective and harmless ointment in the treatment of Scabies, Itch and Acne Rosacea based on the original formula.

Any interested parties are urged to report to The Tilden Company, New Lebanon, N. Y. or St. Louis, Mo., any infringement by others of the Trade Mark DANISH OINTMENT and such information will be acknowledged suitably.

Write for Reprint J. A. M. A., March 4, 1933. Adv.

the right and left lumbar sympathetic ganglia; colopexy; the methods making use of ileo-sigmoidectomy and ileo-rectostomy, with or without exclusion of the redundant loop of colon; sigmoido-sigmoidostomy; all methods inferior to segmental colectomy, the method of choice presenting the minimum of risks.

Preparation for operation lasts 7 days. First day: purgation with castor oil, and each day following, a gentle laxative. The food taken during this period will be easy to digest and of a type which leaves but little residue. Plenty of liquid in order that the patient does not become dehydrated.

Technique: The Authors describe the most frequent type of case, resection of the redundant loop of sigmoide.

1st. Left-side MacBurney Incision.

2nd. Exploration: to remove completely from the abdominal cavity the exeburant pelvic loop.

3rd. Placing of a supple clamp on the mobile side of the loop, and a Kocher forceps on the other side, the two instruments 4 cms. apart. Careful preventive hemostasis.

Section of the intestine by scalpel close to (or nearly level with) the Kocher forceps.

4th. End-to-end anastomosis, "margin-to-margin" or "border-to-border" of Robineau, the sutures being carried from left to right, and using catgut 00 or linen thread, and a needle at each end.

The Authors describe in details the posterior and anterior musculo-serous and muco-mucous whipstitches.

5th. Careful closure of the mesocolic breach.

6th. Exteriorization of the anastomosis. Two catgut stitches are passed to unite the parietal peritoneum of the angles of the wound with the intestine at a distance of about 4 cms. from the anastomosis at either end, to the level of the colic longitudinal band, if possible. Two large gauze packs are slipped between the two lips of the incision and the intestine. If possible, re-enforce the anastomosis by applying to it a layer of omentum.

7th. Dressing applied on the intestine, vaseline compresses or oily tulle, in order that the intestine and the sutures do not adhere to it.

Post operative cure. Liquid diet for 6 days; subcutaneous saline. Keep patient constipated for 8 days. Purgation the 10th day. Gauze packs removed the 6th day.

Operative and late results of five cases: Case I. Anastomosis enters within the abdominal cavity at the end of 8 days. Parietal suppuration cleared up on the 15th day.

Case II. Small stercoral fistula cleared up on the 15th day. Cicatrization on the 30th day.

Case III. Patient 62 years of age. Loosening of the sutures over the an-

terior semi-circumsference. Fistula closed in a second stage. Treatment required 45 days.

Cases IV and V. Ideal operative results.

Late results. The three last cases are too recent to draw useful conclusions. The first case was done 3 years ago, and the second, 2 years ago. Both of these patients are very satisfied, less constipated, no further painful crises or swellings, the signs of intestinal intoxication have disappeared.

Advantages of this technique. Superior to the classic colotomy in one stage, which by a possible loosening of the sutures may result in an acute peritonitis. Superior also to the colectomy in several stages, a sure but complex method requiring prolonged hospitalization and necessitating furthermore the making of an artificial anus, the cure of which is sometimes dangerous.

As one is able to gather from the detailed observations of the Authors, the technique recommended by them has the advantages of the two classic procedures without their inconveniences. The technique is simple, the operative results rapid and sure, and the possible rupture of the anastomosis does not expose the patient to any vital danger.

Acute Appendicitis. A Study of the Correlation Between the Time of Operation, the Pathology and the Mortality. S. G. and O., Vol. LIX, No. 5, pp. 738-744, Nov., 1934

After having reviewed some recent publications on appendicitis, and after having analyzed and re-analyzed his own, as well as the reported cases of appendicitis during the last twenty-six years, the Author has shaped two functional truths which he believes can be confirmed by any surgeon of experience. The first is that the operative mortality of acute appendicitis bears a definite relationship to the duration of the inflammatory process prior to operation. The mortality increases with the duration of the process up to the fourth and fifth days, which are about the same, after which it falls in a curve almost the mirror image of its rise. The ideal solution of that problem would be to have all patients come to operation during the first twenty-four hours of the attack, but as long as human nature and human judgment remain what they are surgeons will continue to be called upon to treat a considerable number of late cases of appendicitis.

The second basic point is that the mortality is inseparably associated with a corresponding sequence of changes in the inflammatory process itself. During the first day the peritoneal reaction is one of engorgement with little exudate. During the second day there is engorgement and leukocytic infiltration with roughening of the peritoneum. Experience has shown that at this stage the peritoneum is still able to take care of whatever infection there may be after the appendix is removed. During the third day the exudate is distinctly purulent, fibrin is abundant and organization has begun. By the fourth and fifth days the process of organization is well advanced so that the process is somewhat encapsulated. At this stage it is usually multilocular and not drainable; later a single cavity results. As the age of the process increases now, the extent of the peritoneal process diminishes and the mortality rate falls.

In the Author's experience the Ochsner treatment during the high mortality period of the disease has been safe, and technically easy and satisfactory in every way, but it has been morally very difficult not to operate upon most patients as soon as referred. In retrospection the Author believes that he cannot see how he might have materially reduced his mortality rate by employing the Ochsner treatment in a larger number of cases.

N. M. Percy, Chicago.

CHECK PUTREFACTION with

• KARICIN •

Detoxification of the bowel contents with Karicin is effective in relieving the symptoms of intestinal toxemia, mucous colitis and putrefaction.

Not a laxative — Not an antiseptic.

DOSE: The average dose of Karicin is a tablespoonful three times a day, taken in water or milk at least one hour before or one hour after meals.

Write for clinical sample and literature.

TEN MILKS for INFANT FEEDING *but* KARO *is a UNIVERSAL MODIFIER*

	Milks	*Indication*
1	Whole Milk	Normal Feeding
2	Skimmed Milk	Infection Vomiting Diarrhea
3	Top Milk	Malnutrition Constipation
4	Soft Curd Milk	Intolerance Indigestion
5	Evaporated Milk	Prematurity Marasmus Eczema
6	Dried Milk	Intolerance Allergy Travelling
7	Acid Milk	Marasmus Diarrhea Celiac Disease
8	Protein Milk	Diarrhea Celiac Disease
9	Butter-Flour Mixture	Marasmus
10	Goat's Milk	Allergy

ARTIFICIAL feeding consists of cow's milk modified to the degree of adequacy of breast milk. The types of formulæ devised appear different—but successful mixtures contain approximately the same distribution in protein, carbohydrate and fat. Two-thirds of the total calories are supplied in milk and one-third in added carbohydrate. The formulæ contain 10-20% of the calories in protein, 20-30% in fat and 50-70% in carbohydrate.

Most infants tolerate whole milk. But those with irritable gastro-intestinal tracts, limited digestive capacities or allergic sensitivities, require milk adapted to their low tolerance. As a result, milk has been altered chemically in various ways to make it especially suitable for each type of infant feeding problem. The adjacent column reveals indications for various milks.

But the ten milks available for infant feeding can be safely modified with Karo. It is adapted to every type of formula devised. Karo consists of dextrins, maltose and dextrose (with a small percentage of sucrose added for flavor) practically free from protein, starch and minerals. Karo is a non-allergic carbohydrate, not readily fermentable, well tolerated, readily digested, effectively utilized and economical for both the baby and the budget.

Corn Products Consulting Service for Physicians is available for further clinical information regarding Karo. Please Address: Corn Products Sales Company, Dept. D. N. 3, 17 Battery Place, New York City.

No Undue Influence on the Bowel~

But Dependable EFFECTIVE CHOLERESIS

The principal therapeutic action of Decholin is upon the liver cells, increasing secretion of bile 100 to 200%. True choleresis is thus obtained without the use of phenolphthalein, cascara, or other laxative drugs usually found in so-termed cholagogues. Repeated purgings, of little or no benefit to the patient, and often harmful instead, are obviated, with no diminution in therapeutic efficacy. The intense and sustained choleresis as obtained with Decholin is of established value in chronic cholecystitis, cholangitis, hepatitis, catarrhal jaundice, and functional hepatic insufficiency and intoxication.

REG. U.S. PAT. OFF.

An Intestinal Antiseptic of Proved Performance

Whatever the causal agent of Ulcerative Colitis may be, we know that the intelligent use of Alpha Naphco has a *remedial effect quite* beyond expectations, except to those physicians who have given it an exhaustive trial.

ALPHA NAPHCO in water or orange juice

JELLY of ALPHA NAPHCO in Capsules

In Amoebic Dysentery and in Amoebiasis without frank diarrhea, the use of Alpha Naphco in liquid or capsule form has a definite place in the armamemtarium of the gastroenterologist,—it brings results as testified by a growing list of clinical investigators. These striking results may be due to the influence of the preparations upon the secondary invaders, whose importance is well recognized. In seasonal diarrheas, due to B. dysenteriae, or B. welchii, and in cases where the etiology cannot be readily discovered, Alpha Naphco therapy is winning a prominent place, both as an independent agent and as a most valuable adjunct to other forms of specific medication.

Exhaustive clinical and animal experiments have conclusively demonstrated the non-toxicity of the preparations... On receipt of your letter head or a page from your prescription book we shall be glad to send you supplies for clinical test and condensed reports.

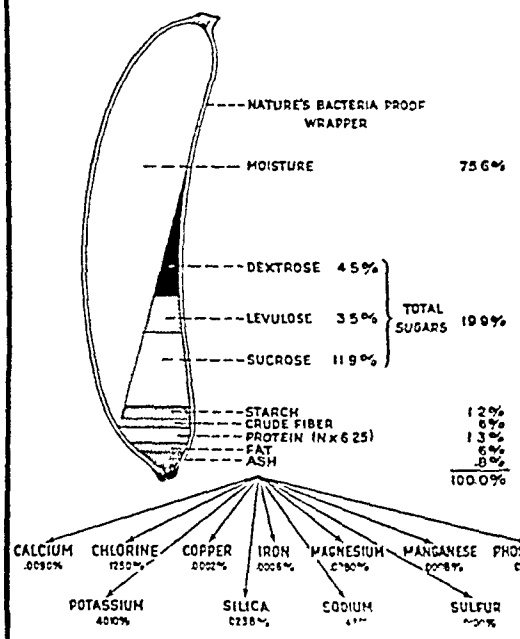
Why RIPE BANANAS are naturally suited to the treatment of gastric disorders

Easily Digested... Non-irritating ..Good source of food energy, vitamins, minerals... Pleasant taste

RIPE BANANAS are an easily digested, bland food which supplies essential vitamins and minerals, and is popular with most patients. They are non-irritating... do not ferment easily in the intestines... and create intestinal conditions unfavorable to the growth of putrefactive bacteria.

The carbohydrates of a ripe banana comprise about 22% of its total weight when peeled. They consist chiefly of a mixture of sugars—sucrose, dextrose, and levulose—which are readily absorbed, even by infants and young children with gastro-intestinal disturbances.



Besides being an excellent source of food energy, bananas are a good source of Vitamins A, B, C, and G, contribute to the diet important minerals and yield alkaline mineral residues in the body. With their soft fiber, pectins, high content of sugars, low content of protein and fat, and their vitamins, bananas seem adapted to act as a normalizer of colonic functioning.

UNITED FRUIT BANANAS

It's easy to have Ripe Bananas all the time

BANANAS ripen naturally at room temperature. If they are partially ripe when purchased—i. e., in the green-tipped stage, they should be kept at comfortable room temperature (never in the refrigerator) until the pulp has softened and the skin is golden yellow flecked with brown. That is when they're fully ripe and at their very best in flavor.

"... we know that in the infant and growing child alkali in excess of acid must be stored."

Growth and Development of the Child, Part III, White House Conference on Child Health and Protection, New York, 1932, p. 213.

BUT— many diets are acid-forming

AS pointed out in the Journal of the American Medical Association (Queries and Minor Notes, 103:701, 1934), "... most high carbohydrate foods of the artificial and refined types are lacking in the basic elements. These basic ions, such as sodium, potassium, and calcium, are necessary for the neutralization and excretion of the various acid waste products of the body. Hence carbohydrates may be implicated in the occurrence of such an acid state by displacing other necessary food products from the dietary."

Ordinary cereals and cereal products, meat, and eggs—all produce an acid ash when burned in the body, yet they form the mainstay of the average diet. Although this preponderance of acid-forming foods is not definitely known to have great significance for the health of normal adults, a number of authorities advocate a basic or alkali-forming diet for children and pregnant women.

INFANCY AND CHILDHOOD. "Alkaline diets are essential for infancy where growth is rapid," declares Shohl. *He calculates the need as 10 cc. excess of 0.1 normal base per kilo per day.*[1] *Babies fed on* breast milk stored an excess of base over acid, the range being from 31 to 56 cc. 0.1 N base per day, is the finding of the Committee on Growth and Development of the White House Conference on Child Health.[2] Lippard and Marples observed greater increases in weight of infants receiving basic diets as compared with controls on acid-forming feedings.[3]

PREGNANCY AND LACTATION. Shohl states, "Pregnancy and lactation require additional alkali—a minimum of 150 cc. 0.1 N base per day."[1] Coons and associates, from acid-base balances taken upon normal pregnant women receiving basic diets, determined that the storage of basic substances was even greater than estimated by Shohl. "This may be some indication," they say, "of the magnitude of the maternal needs exclusive of fetus."[4]

As the chief alkali-forming foods are fruits, vegetables, and milk, the ordinary basic diet consisting of these foods is likely to be low in calories and often does not appease hunger. But Pablum—the only base-forming cereal*—offers a way to add muffins, cereal, puddings and similar "filling" foods to the usual basic diet. Pablum, moreover, is richer than ordinary cereals in calcium, phosphorus, iron, and copper and supplies vitamins A, B, E, and G.

[1-4] *Bibliography on request.* *Mead's Cereal (Pablum in uncooked form) is also base-forming.

MEAD JOHNSON & COMPANY, - - - Evansville, Indiana, U.S.A.

Pablum (Mead's Cereal thoroughly precooked) is a palatable basic cereal consisting of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa leaf, beef bone, brewers' yeast, iron salt and sodium chloride.

Cereal	Base	Acid
PABLUM	1.8	
Farina		11.0
Oatmeal		12.9
Wheat, whole		11.5
Cornmeal		5.3
Barley		10.1
Rice		8.1

Figures given in the above table are based on 100 grams of food and represent cubic centimeters of normal acid or base.

EXICOL

INDICATED in hepato-biliary disorders when dependable cholagogue and choleretic action is desired.

In prescribing Exicol you have the advantage of an effective therapeutic agent checked in the animal laboratory and clinically.

Exicol therapy is based on latest known and accepted physiologic principles governing the biliary apparatus.

ACTION: 1. It stimulates gall bladder evacuations (Cholagogue) and
2. Increases bile flow from the liver (Choleretic).

DOSE: 2 capsules t.i.d.a.c.

In boxes of 36 and 100.

SECTION I—*Clinical Medicine: Diseases of Digestion*

The Relation in Man Between Gastric Acidity and Height and Weight*

By

FRANCES R. VANZANT, M.D.**
WALTER C. ALVAREZ, M.D.†
and
JOSEPH BERKSON, M.D.‡
ROCHESTER, MINNESOTA

THIS paper represents one of a series of studies of gastric acidity in normal men and women (1, 2, 3, 4, 5 and 6). We are dealing here with the relations of height and weight to free gastric acidity in persons without demonstrable disease of the stomach or duodenum. In making this study we were moved with the desire not only to answer questions that might well be asked by the physiologist or the physical anthropologist, but also to find out if, when comparing mean acidity in two groups of persons, it is advisable to take account of height or weight, or of the degree of thinness or fatness. So far we have not been able to find an adequate answer to these questions in the literature.

For the purpose of this study we picked out from the large mass of data previously used in establishing standards of normal, all those records made on patients who had free acid and for whom note had been made of the height and weight. This selection left us with 2,185 records, 1,228 from men and 957 from women.

GASTRIC ACIDITY AND WEIGHT

In order to see if acidity varies with weight, each person's free acidity was expressed as the difference, plus or minus, between his reading and the normal average for his or her age and sex. These data for men and women separately were then divided into groups representing intervals of 10 pounds (4.5 kg.) in the weight of the persons studied, and in each of these groups the mean deviation in acidity was calculated and plotted as in Figure 1 *B*. Obviously, if there had been no relation between acidity and weight these averages would have all been approximately zero and would have fallen in a straight line running horizontally across the page. Actually, it will be seen that in both men and women there was a small increase in mean acidity with increasing weight, an increase which was more marked in women than in men. In women it amounted to about 0.08 units per pound and in men to approximately 0.06 units per pound. The coefficient of correlation between weight and acidity in this series of observations was, for the women, $+0.346 \pm 0.019$, and for the men, $+0.066 \pm 0.015$.

GASTRIC ACIDITY AND HEIGHT

In looking for a relation between gastric acidity and height the procedure was much the same as that just described; the only difference was that the data representing deviations from normal acidity were divided into groups according to intervals of 2 inches (5 cm.) in the height of the persons studied. Figure 1 *A* shows that in the men there was a rise of 0.8 unit of acidity for each inch of height. No such variation could be found in the case of the women. The coefficient of correlation for the men was $+0.090 \pm 0.019$ which, although very small, is statistically significant. In women the figure was -0.009 ± 0.022 which is not statistically significant.

THE RELATION OF GASTRIC ACIDITY TO NORMAL WEIGHT AND HEIGHT

Unfortunately the data just presented leave several questions unanswered. As we have shown elsewhere, (2, 5) gastric acidity varies with age, and since height and weight also vary with age the question arises: How much of the change in acidity with weight and height is due to the changes in age? If one could study a group of persons all of approximately the same age and height, would gastric acidity still vary with weight, and if so, to what extent? The same questions arise as to the relations between acidity and height in a group of persons of approximately the same age and weight. In other words, we wanted to compare acidity, not with weight alone, but with the degree of fatness or thinness, and similarly, we wanted to study the influence of tallness and shortness.

If we had had thousands of records at our disposal we might have obtained answers to our questions by an analysis of data from groups of persons of the same height (and weight) and age, but even with 2,185 records the method was impracticable because, with three variables to study in men and women separately, the resultant groups would have been too small for reliable statistical analysis. Ordinarily, when faced by such a situation, the statistician uses all his data and

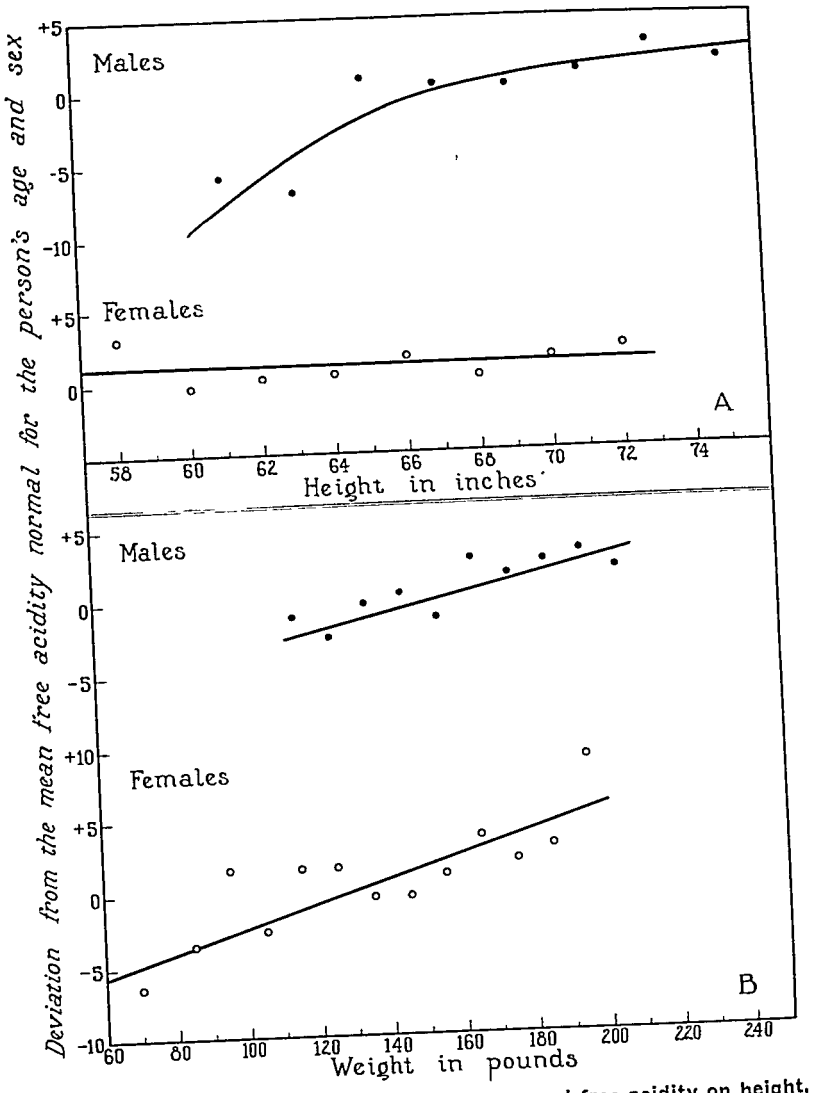

Fig. 1 A. Regressions of deviations from normal free acidity on height, in men and women; B, Regressions of deviations from mean gastric acidity on weight, in men and women.

employs the method of partial correlation, but this can be applied only when the relation of all the variables is strictly linear, and this was found not to be the case with our data, when they were submitted to Blakeman's test.

We first attempted to obtain an answer to the problem by comparing in each case the deviation from the normal standard of acidity with the deviation in weight from the figure given in an insurance table for a man or woman of the given height and age, but a critical analysis of this method showed that it is open to objections. If the insurance standards of height and weight should happen not to apply to the persons included in our study, results might be obtained that would lead to false interpretations respecting the relation of gastric acid to height and weight. Furthermore, one must adhere strictly to certain details in the calculations if the results are to be comparable with those obtained with the use of the partial correlation technic. Accordingly, a method was evolved which is somewhat more elaborate, but gives, we believe, practically the same results for our data as would be obtained by partial correlation if the regressions were linear.

In simple words, we began by preparing a nomogram to give the relationships between age, weight, and height for each sex in our own group of 2,185 persons under investigation. In making this, the data for each sex were separated into groups representing intervals of five years in age, and within each of these groups average weight was plotted against height, and average height against weight. Regression lines were fitted graphically and the height of each man or woman was then expressed as a plus or minus deviation in inches from the mean height for his or her weight and age as determined by the point through which the regression line passed. In the same way individual weights were expressed as deviations in pounds from the mean weight for the given age and height.

These records were then collected in groups representing intervals of 1 inch of deviation from average height and also in groups representing intervals of 10 pounds of deviation from average weight. In each of these groups we next obtained and plotted, as in Figure 2 *A* and *B*, the mean deviation from normal

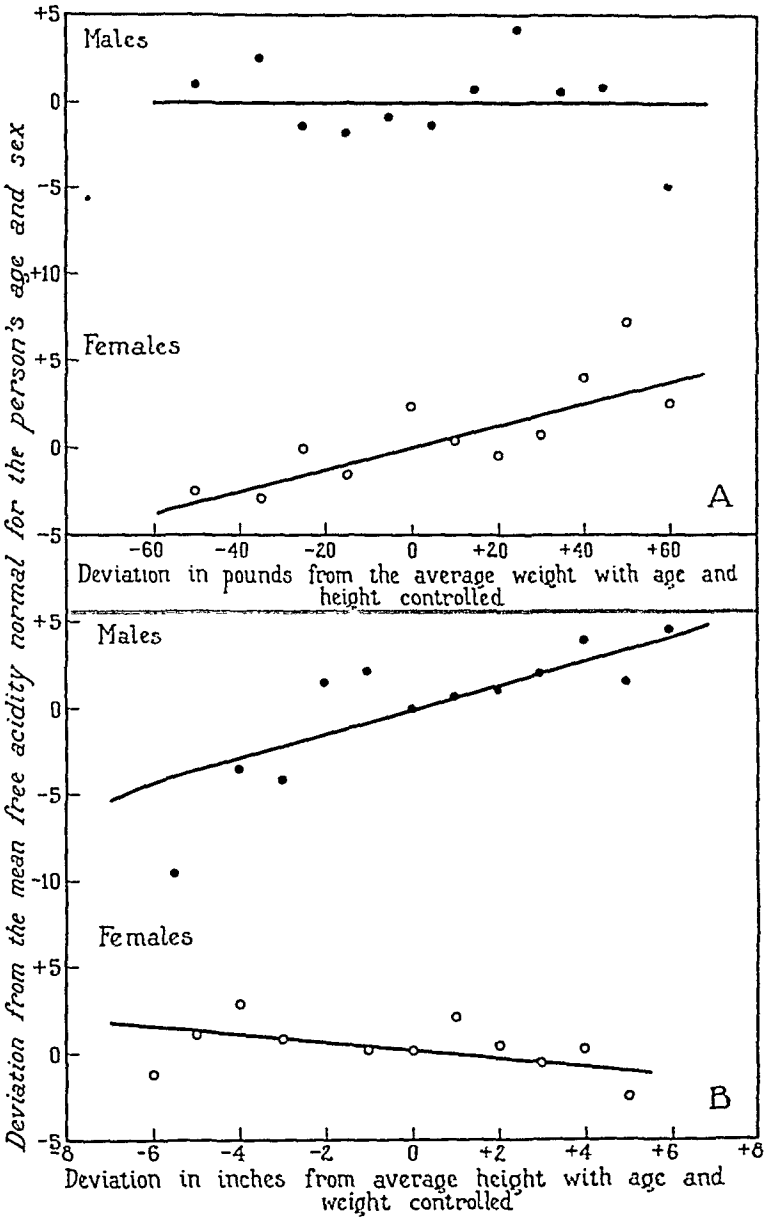

Fig. 2 A. Regressions of deviations from normal free acidity on deviations from average weight with age and height controlled; B, Regressions of deviations from normal free acidity on deviations from average height with age and weight controlled.

free acidity. As the reader will recall, these deviations were obtained by expressing each person's acidity as a difference from his or her normal standard.

It will be seen from Figure 2 *A* that with age and height controlled, there was in women a definite increase in mean gastric acidity with increasing weight amounting to approximately 0.06 units for each pound. Strange to say there was no such relation in the case of men.

Figure 2 *B* shows that in men, with age and weight controlled, gastric acidity increased approximately 0.08 units for every added inch of height. In women there was a slight trend in the opposite direction, amounting to a lessening of acidity of 0.02 units for each added inch in height.

COMMENT

In some work on dogs Vanzant found that when they were fed a standard meal of meat and water the smaller animals tended to have lower curves of acidity than did the larger ones. When, however, the size of the test meal was made proportional to the weight of the dog the response of all the animals was practically the same. It was thought that the larger dogs, with their larger stomachs, would have a larger secreting surface, and perhaps therefore a larger amount of acid to be diluted by the fluid in the standard meal.

Actually this explanation is not adequate to account for the differences seen in the case of man where, during the period between birth and maturity, the body weight increases from twelve to twenty times, the surface area of the gastric mucosa about seventeen times (7), the number of gland mouths about twenty-five times, the number of gland bodies about twelve times (8), and the mean gastric acidity only four or five times. Similarly, with women, the difference between the mean free gastric acidity of those weighing

100 pounds and those weighing 200 pounds is only about 8 units.

The correction factors for differences in bodily build are so small that they need hardly be taken into account unless, when comparing mean acidity in two groups of persons, their mean weights are very different or their mean acidities are very nearly the same. Thus if one group of women were to weigh on the average 20 pounds more than another group, the difference in mean free acidity due to this factor alone would be only 1.2 units.

SUMMARY

A study of 2,185 normal persons showed that, with age and height constant, free gastric acidity increased in women 0.06 units for each added pound of weight. There was no such relation in the case of men. With age and weight constant, free gastric acidity increased in men 0.08 units for each added inch in height. In women the acidity was lowered by 0.02 units for each added inch.

The differences in gastric acidity observed in men and women of widely divergent build are so small that in ordinary practice an allowance need not be made for them.

A simple method of studying multiple correlations when the regressions are non-linear is described.

New Clinical Concepts of Bacillary Dysentery: Its Relationship to Non-specific Ulcerative Colitis, Distal Ileitis and Non-specific Granuloma.*

By

JOSEPH FELSEN, M.D.

NEW YORK, NEW YORK

THE following data (1) are from studies made in the eighteen month period from December, 1933 to June, 1935, of 317 cases of acute bacillary dysentery, 11 cases of acute distal ileitis, 42 consecutive cases of non-specific ulcerative colitis, 8 with chronic distal ileitis, 4 with pseudo-polyposis (polyposis cystica of Virchow) and 2 cases of non-specific granuloma of the ileocecal region. A follow-up is included in this study and the evidence is presented in an attempt to show that acute bacillary dysentery, acute distal ileitis, chronic non-specific ulcerative colitis and ileitis and non-specific granuloma are but different stages of the same disease.

Typical Acute Bacillary Dysentery. The typical case of acute bacillary dysentery presents intestinal manifestations and systemic toxic effects which are prominent, easily recognized and require only bacteriologic study for accurate corroboration. The patient is placed on typhoid precautions, an epidemiologic survey is made and in the average mild or moderately severe case the disease runs its course in approximately seven to ten days with complete recovery. Only certain features, frequently overlooked, will be stressed. First, the incubation period is often a matter of hours rather than days. In two specific instances where the actual contact was proven, one of Flexner and another of Sonne-Duval, the incubation period was approximately 14 and 10 hours respectively. Second, the highly toxic Shiga type of dysentery is relatively infrequent in the United States but the Flexner group may sometimes be found to equal the former in toxicity, to say nothing of the occasional instances of sudden death in the comparatively mild Sonne-Duval type. Third, acute multiple arthritis is a rather common complication of bacillary dysentery and often persists in the chronic stage (12% in our series. See Table I). Fourth, the diagnostic laboratory criteria are positive fecal culture during the first week and bacteriophage and rising agglutination titre after the first week. Also, an initial leucopenia is relatively common in acute bacillary dysentery. We have seen counts as low as 3600 in moderately severe cases with complete recovery. Fifth, local as well as national statistics on bacillary dysentery are incomplete because intramural institutional outbreaks are neither properly studied nor are the clinical manifestations easily recognized by the physician who sees the atypical epidemic or sporadic cases. We shall refer briefly to these atypical types.

Atypical Acute Bacillary Dysentery. 1. Neurotropic type. Symptomatology resembles that of meningococcus meningitis but the spinal fluid findings are negative. The patient has or soon develops an intractable diarrhea. Nasal or labial herpes is present. 2. Appendicular type. Symptomatology resembles that of

*From the Department of Laboratories and Medical Research, Bronx Hospital, New York, N. Y.

Submitted August 15, 1935.

acute suppurative appendicitis but at operation the appendix is found to be normal. There is seen, however, an acute diffuse mesenteric lymphadenitis and usually an acute segmental inflammation of the distal ileum. A normal leucocyte count or leucopenia, pain and tenderness in the ileocecal region without abdominal rigidity, and the presence of spastic ileum or sigmoid are the chief differential features. The occasional association of an upper respiratory infection with mesenteric lymphadenitis in acute bacillary dysentery in children is noteworthy. 3. Afebrile type. 4. Asymptomatic type. These patients are not carriers. 5. Constipated type. To these types, the recognition of which is so important in the epidemiology of the disease and its relationship to chronic intestinal

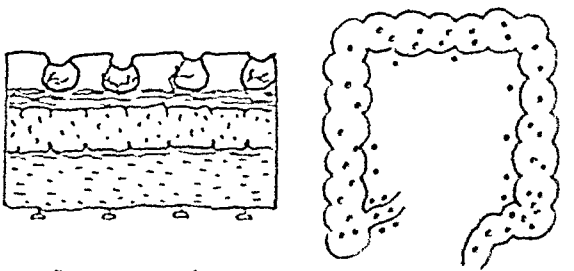
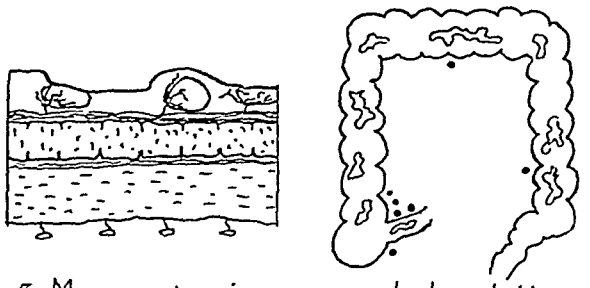
Diagnostic titres 4.6% (all types). None against S-D.



Acute bacillary dysentery

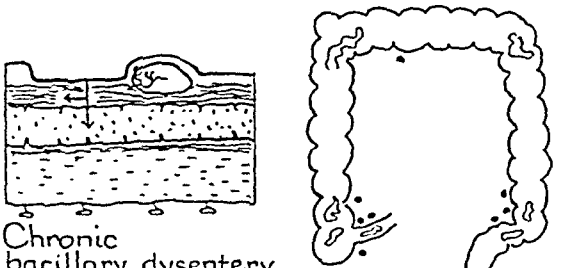


1. Stage of congestion, hyperemia and lymphoid hyperplasia; acute distal ileitis, mesenteric and mesocolic lymphadenitis.

ulceration, there may now be added another type, viz., 6. Acute fulminating type with malignant neutropenia. The two cases thus far encountered were of the Flexner and Mt. Desert types, the disease running its acute course to a fatal termination in three to four weeks. Advanced ulcerative ileocolitis with pseudo-polyposis was present in both cases, the toxemia was profound and was associated with a progressive decrease in leucocytes and neutrophiles and marked toxic changes in the latter. There was extreme dehydration with a misleading hemoglobin-erythrocytic picture due to blood concentration. In one case a Vincent's infection of the mouth was definitely present, in the other no examinations for the organisms were made although mouth lesions were present. The association of the neutropenia with the Vincent's infection is possible but our frequent observation of marked leucopenia in other cases of acute bacillary dysentery without a secondary Vincent's infection militates against this relationship. It appears rather to be due to destruction of the granulocytes by the dysentery toxin in the peripheral blood or to a toxin effect on the vascular sinusoids of the bone marrow into which the granulocytes must pass after their extravascular formation. This is further supported by the finding that bone marrow sections showed no lack of production of granulocytes. We have noted similar effects upon the blood vessels and reticulo-endothelial tissue of the intestine in humans and animals.

Relationship of Acute Bacillary Dysentery to Chronic Ulcerative (Non-specific) Colitis, Distal Ileitis and Non-specific Granuloma. Bearing in mind the facts briefly alluded to above regarding the typical and atypical phases of acute bacillary dysentery it may be readily understood why much confusion has arisen with regard to the other diseases named. It is due chiefly to: 1. Non-recognition of the disease in the acute stage. 2. Lack of adequate follow-up of the diagnosed cases. It is the latter upon which we must

2. Focal lymphoid necrosis with punctate ulceration and superficial mucosal denudation



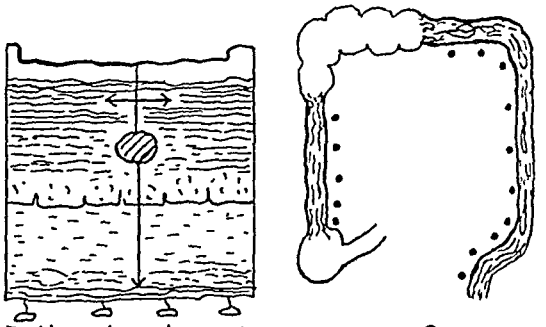
3. More extensive mucosal denudation. Confluent ulceration.

rely chiefly and, supplemented by a thorough knowledge of the underlying pathology, accurately link the acute and chronic stages hitherto regarded as specific and independent diseases. To this end we have followed up our acute dysentery cases and with the information thus gained have studied or re-studied our cases of chronic non-specific ulceration. Each case was investigated as follows: General physical examination with special reference to abdominal masses and intestinal spasm, fecal or sigmoidoscopic culture, diagnostic bacteriophage, agglutination titre, examination for endamoeba histolytica cysts and trophozoites, sigmoidoscopic examination, roentgenographic study of the intestinal tract and epidemiologic investigation. The follow-up was along the same general lines. Young children were not sigmoidoscoped as a rule and roentgenographic examinations were made only in those acute cases where some indication existed. This data may be briefly summarized as follows:

1. Most of our cases of acute bacillary dysentery recovered completely in ten days to two weeks.

2. Acute distal ileitis appeared to subside but in some cases the intestinal lesion persisted. In one child a mass was still palpable at the end of four months, associated with recurrent attacks of bloody diarrhea.

3. Cases of acute baciliary dysentery lasting for more than three weeks appeared to persist by reason of a secondary non-specific infection. Seven patients followed from the time of their initial dysenteric infection had the typical signs and symptoms of non-specific ulcerative colitis at the end of approximately 1, 1, 1, 1, ¾, 1 and 1 year respectively. One patient (Case 14, Table I) had an acute inflammation of the distal ileum and cecum with mesenteric lymphadenitis for which a laparotomy was done in January, 1930. A typical chronic non-specific granuloma was removed three years later at the Bronx Hospital. The interval period was characterized by periodic attacks of bloody and mucoid diarrhea and abdominal cramps.



Chronic bacillary dysentery

4. Acute lesions have not entirely subsided. Secondary non-specific intramural infection begins (probably after third week)

4. In six cases of non-specific ulcerative colitis seen for the first time at varying periods after their initial acute infection definite contact infection was demonstrated suggesting that non-specific ulcerative colitis is transmitted only during the initial stage—namely, that of acute bacillary dysentery.

5. In forty-two consecutive cases of non-specific ulcerative colitis a diagnostic agglutination titre against B. dysenteriae was obtained. In control studies (2) of 300 persons in the New York City area without a history or clinical evidence of dysentery only 4.6% of diagnostic titres was demonstrated. The colitis and control groups were studied by the same method and identical dysentery strains. Eighteen hour broth

Fully developed non-specific ulcerative colitis

5. (a) Inflammatory polyposis with massive geographic and serpiginous mucosal denudation
(b) Mural fibrosis with loss of haustration. Often segmental.
(c) Stenosis of lumen of bowel.
(d) Extensive mural infection, intramural abscess, perforation.

cultures of smooth agglutinable strains, four hours incubation at 55 C. and overnight ice box incubation were used. In certain cases, as specified in Table I, diagnostic phage or positive fecal culture was demonstrated. In one case, a physician with a history of ten years standing, a resection had been done for chronic distal ileitis. Examination of the gross specimen and microscopic sections showed the typical lesion, and phage and culture was positive for B. dysenteriae, Flexner. He had been having recurring attacks of diarrhea with only temporary remissions both pre- and post-operative for ten years.

6. Of the cases included in this report a pathologic study was made of seven specimens of acute bacillary dysentery, eleven of acute distal ileitis*, six of chronic distal ileitis, two of non-specific granuloma and seven of non-specific ulcerative colitis. The lesions in the chronic stage were identical with those seen in acute bacillary dysentery except that owing to the long duration of the disease extensive fibrosis and intramural infection were present. The former represented Nature's attempt at healing and accounted for the loss of haustration and stenosis seen in chronic distal

*Observations at the operating table, sections of mesenteric nodes and appendix supplemented by cultural studies.

ileitis and non-specific ulcerative colitis. Non-specific granuloma of the ileocecal region represents a productive type of inflammation and, like chronic distal ileitis, almost always shows giant cells in the tissue sections. This condition may be erroneously diagnosed as tuberculosis but tubercle bacilli are absent and guinea pig inoculation of the macerated tissue proves negative. The transition stages from the acute enterocolitis of bacillary dysentery to the chronic non-specific lesions are diagramatically shown in Figures 1-7. The acute or chronic lesions may show segmental involvement of the jejunum or ileum, the former being rare.

7. While no case of amoebic dysentery has been included in this study it appears quite probable that the same type of secondary non-specific infection might occur. Those cases with distal ileitis, however, cannot be included as the endamoeba histolytica does not attack the terminal ileum. No case of double infection with both bacillary and amoebic dysentery has come to our attention. Two cases of double infection with typhoid and Sonne-Duval dysentery were seen. Both patients recovered completely.

TABLE II

Agglutination Titre in 11 Cases of Acute Distal Ileitis with Mesenteric Lymphadenitis

Patient	Durntion (days)	Titre	Fecal Culture
1	8	F 1:100	Flexner.
2	21	F 1:100	Flexner.
3	10	F 1:100

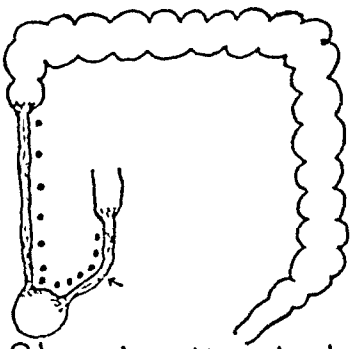
5	7	S-D 1:160	S-D phage and culture.
6	2	S-D 1:100	
7	1	S-D 1:640	S-D.
8	14	F 1:160	
9	1	F 1:100	
10	1	F 1:100	
11	14	S-D 1:100	

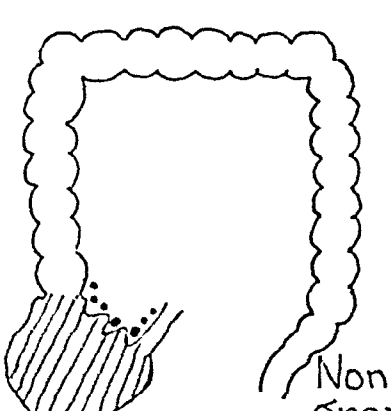


SUMMARY

Flexner: 6; S-D: 5.

Abbreviations: P-H (Park-Hiss strain), Mt. D (Mount Desert strain), S-D (Sonne-Duval strain), F (Flexner strain), J. C. (Jersey City strain) (Flexner). It should be noted that while 1:100 is generally regarded as a diagnostic titre in bacillary dysentery, only 1:40 or 1:50 is required for the S-D strain.

8. Attention is called to the peculiar "stooped-over" or mendicant's posture exhibited by many long standing cases of non-specific ulcerative colitis.



Treatment. The ideal treatment of non-specific ulcerative colitis and its related lesions appears to be the prevention of bacillary dysentery. Recognition of the typical and atypical forms of the disease, prompt isolation and careful epidemiologic surveys should, so far as our studies indicate, lessen the incidence of the diseases known as non-specific ulcerative colitis, chronic distal ileitis and non-specific granuloma. Basically, it is a public health problem. At the Bronx Hospital we suggested paying the nursing and lay staff relieved from duty because of diarrhea so that there should be no hesitancy in reporting for examination. Monthly surveys are being made of all foodhandlers. Institutional outbreaks are frequent because they are not recognized or studied, because the management dislikes the publicity or because employees hesitate to report sick for fear of losing their pay. Every patient with diarrhea or a history of diarrhea should be placed on typhoid precautions until proven free of B. dysenteriae. This is particularly important among children.

Chronic distal ileitis

6. A stenosing, obstructive lesion with fibrosis. Granulomatous giant cells often present. May be mistaken for tuberculosis.

Most cases of acute bacillary dysentery recover without any specific therapy. Supportive treatment, daily doses of castor oil to favor elimination of the toxin and intravenous infusion of 5% dextrose in saline or transfusion for dehydration and toxemia may be used when indicated. The use of recently recovered cases as donors is suggested in the acute severe types of the disease. All patients with acute bacillary dysentery in whom the intestinal lesions persist for more than three weeks should be placed immediately upon prophylactic D-C vaccine and antivirus therapy. In sporadic or epidemic outbreaks the widespread use of polyvalent dysentery vaccine should afford some degree of immunity *before* the patient becomes infected. This observation is based upon a limited experience with human contacts and experimental animals. Some cases of non-specific ulcerative colitis heal spontaneously but most of them go on for years with periodic stages of remission and exacerbation. For the latter we have outlined a course of therapy which has proved quite efficacious. It must be remembered that all we can hope for in a case of long duration where the intestine is really nothing more than a tube of vascularized connective tissue free of protective lymph nodules and with diffuse infection or intramural abscesses, is subsidence of the infection. Towards this end we use the following therapy: 1. Intestinal oxygenation. 2. D-C

Non-specific granuloma

7. Productive type of inflammation Granulomatous giant cells may be present.

vaccine. 3. D-C antivirus. The organisms in the vaccine and antivirus include polyvalent strains of the specific dysentery (D) organism with which the patient was originally infected as demonstrated by the agglutination titre, and the two common secondary invaders, enterococcus and B. coli (C). The vaccine and antivirus are administered every other day, the former in gradually increasing dosage after a preliminary skin test for sensitivity. A D-C serum is now in process of preparation for quick passive immunization. Therapeutic phage has proven of little value and surgery of very limited usefulness. Resections in our experience have almost invariably been followed by recurrences because the surgeon cuts through infected bowel. It is surprising how far intramural infection actually extends beyond the grossly visible line of pathology. Surgery is indicated chiefly in acute obstruction. It is preferable to handle the disease by preventing bacillary dysentery, following up the cases that do occur so as to forestall the late lesions which, when they do become manifest, are best treated by the systemic route through which the original infection took place.

Studies on Constitution and Peptic Ulcer

I. Appetite Secretion in Normal Persons and in Ulcer Patients*

By

H. NECHELES, M.D., Ph.D.

and

M. H. MASKIN, M.D.

CHICAGO, ILLINOIS

FOR almost a century, physiologists have accumulated evidence indicating that gastric secretion is markedly influenced by psychogenous stimuli.

In 1833, Beaumont (1) had already suspected a nervous factor in gastric secretion. Some two decades later, Bidder and Schmidt (2) demonstrated that the perception of food sufficed to stimulate a flow of gastric juice, but it was left to Pavlov (3) to recognize this phenomenon as a true cerebral reflex. In 1887, Pavlov and Schumov-Simanovskaia (3) described the now classic "sham feeding" experiments, which utilized esophagotomized and gastrostomized dogs who were allowed to masticate food which, when swallowed, fell out through the peripheral esophageal fistula, thus permitting the collection of an uncontaminated gastric juice.

Analogous experimentation has been done with man as subject. In 1878 Richet (4) detected a psychic secretion in a young man with an esophageal stenosis and a gastrostomy. Subsequent work, reviewed and extended by Carlson (5), Babkin (6), and others (7-8) has established that "sham feeding" of palatable foods will stimulate gastric secretion in man, but that indifferent or repulsive material will not.

The first determination of the volume and acidity of the psychic secretion in an ulcer subject was made by Troller (9) in 1899, who merely demonstrated that a psychic secretion does exist. Subsequently, a number of clinicians (10-14) have recommended the clinical employment of "sham feeding" to detect states of hyperacidity and hypersecretion as well as hyperirritability of the gastric vagus.

In this connection, the theory of Moszkowicz (15) must be mentioned. Basing his conclusions upon the work of Silbermann (16) who produced ulcers in dogs by persistent "sham feeding" he has conceived the thesis that a continuous high acid psychic secretion is the causative agent in peptic ulcer.

TABLE I

Age Distribution in Appetite Secretion Series

Age in Years	Number of Patients	
	Normal	Ulcer
17-20	4	2
21-30	7	6
31-40	10	10
41-50	6	7
51-60	7	7
61-70	1	2
Total	35	34

To our knowledge, no one has described as yet, the comparative appetite secretion between normal subjects and patients with peptic ulcer. The present study represents such an investigation of the appetite secretion of 34 male subjects with duodenal ulcer, the diagnosis of which was established roentgenologically, and of 35 normal men. The age distribution in both groups is practically identical.

METHOD OF PROCEDURE

All individual determinations were performed under similar conditions, in the same room, and at approximately

*From the Gastro-Intestinal Laboratory, Department of Physiology of the Michael Reese Hospital. Aided by the Louis L. Cohen Fund.
Submitted November 11, 1935.

the same morning hour. The subjects were not told the purpose of the investigation.

The preliminary instructions to the subjects were to eat nothing after 10 o'clock the night preceding the test and to drink nothing the morning of the examination.

For the test proper, the patient assumed a comfortable semi-reclining position; a Rehfuss tube was passed into the stomach; and the residual gastric contents evacuated, measured and titrated. At ten minute intervals, in the succeeding half-hour, aspirations were made of the basal stomach secretion, its volume determined, 10 c.c. was retained for titration, and the remainder returned to the stomach.

Following the last control determination, the subject was provided with a chilled orange broken into small pieces, and given instructions to chew the orange slowly, to swallow nothing, and to expectorate the orange pulp, the orange juice, and saliva. The time given for mastication was ten minutes.

Immediately thereafter, the entire gastric contents were aspirated, examined for orange contents, measured, titrated and not returned. Subsequently, at five ten minute intervals and one final 30 minute interval, 80 minutes in all, the stomach was completely emptied, the volume determined, 10 c.c. set aside for analysis and the remainder returned.

The data accumulated in this manner were analyzed statistically (formulae of Fisher 17). The mean free and total acidity and the mean secretion volume for the group of ulcer patients and normal persons respectively were compared before and after the "sham" meal at each of the time intervals specified above. The basal secretion is considered as the average of the last two control specimens before the "sham" meal.

RESULTS

The results obtained can be easily understood from Chart 1, where each point represents the mean of all determinations. It is apparent that the acidity not only rises immediately following mastication of the orange and later returns to a basal level, but also that in a general way the behavior of the ulcer and normal subjects varies only quantitatively. This similar reaction of appetite secretion in both groups is sufficiently consistent to indicate the expression of an intrinsic physiologic mechanism, which is not disturbed by the disease "ulcer," and is shifted to a higher level. This reaction distinctly parallels the response of normal persons and of patients with duodenal ulcer to an Ewald meal, and the curves and explanations given by Vanzant, Alvarez and Eusterman (18) are strikingly similar to these curves of psychic secretion. Even the difference in free acidity, determined by a test meal, between their groups of normal persons and of ulcer patients is quite similar to the difference in the free acidity of appetite secretion observed here.

Table II indicates that no significant difference exists in basal acidity between ulcer and normal subjects, but that the appetite juice collected 10 and 20 minutes after the beginning of mastication is 12.8 and 14.8 degrees respectively higher in free acidity for the ulcer group, and these values are statistically significant. The total acidity reflects this phenomenon, as manifest in the borderline significance of 11.3 degrees difference between ulcer and normal subjects in the first 10 minute specimen.

TABLE II

Appetite Secretion in Normal Persons and in Ulcer Patients

		ACID SECRETION OF STOMACH						
		Before[1]	After Chewing of Orange (in Minutes)					
			10	20	30	40	50	80
FREE ACIDITY	Ulcer Mean	26.1	28.6	35.2	35.7	32.6	33.4	27.4
	Normal Mean	16.9	15.8	20.4	25.7	26.0	23.5	27.6
	Difference of Means	9.2	12.8	14.8	10.0	6.6	9.9	-0.2
	Significance of the Difference of Means	n.s.[2]	±5.09 (s)[3]	±4.8 (s)	n.s.	n.s.	n.s.	n.s.
TOTAL ACIDITY	Ulcer Mean	46.4	61.0	63.9	62.6	57.1	56.3	49.4
	Normal Mean	39.6	49.7	48.5	51.7	50.1	44.1	44.5
	Difference of Means	6.8	11.3	15.4	10.9	7.0	12.2	4.9
	Significance of the Difference of Means	n.s.	±5.9 (s)	n.s.	n.s.	n.s.	n.s.	n.s.

The Acidity is expressed in clinical degrees, i.e. in c.c. of N/10 HCl per 100 c.c. of gastric juice.
[1] Average of two ten minute periods before mastication.
[2] Not significant.
[3] Significant.

The difference in mean volumes never proved statistically significant.

The above results indicate that the ulcer subject reacts excessively to an ordinary stimulus. Further, it appears that human appetite juice is a secretion of only small volume, of short duration (20 minutes) and of moderate acidity, hardly possessing the properties attributed to it by Moszkowicz (15).

The extreme variability in the individual values obtained throughout both ulcer and normal series completely vitiates the significance of "sham feeding" utilized for clinical diagnostic purposes. Undoubtedly

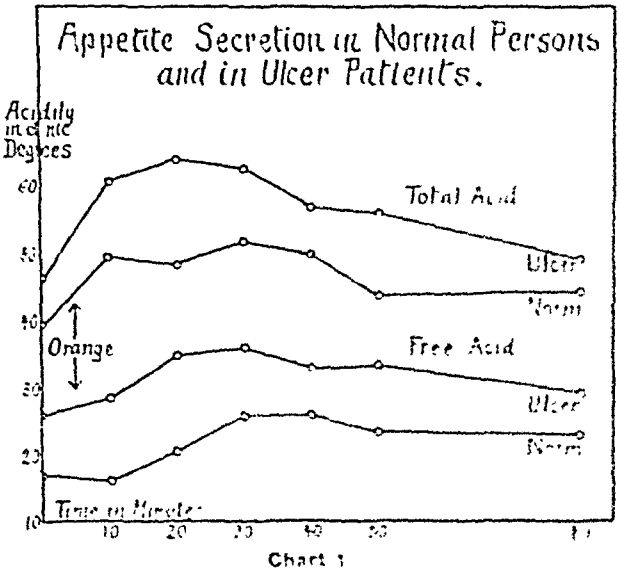

Chart 1

the variability of psychic secretion depends, in considerable measure, upon the methods employed. The foreign environment, the nausea evoked in some subjects by the stomach tube, the relative hunger at the time of the test, the relative preference for the test meal, the frustration experienced in avoiding deglutition and in expectorating the desired food, the difficulty in aspirating very small quantities of gastric juice, the variations in regurgitated duodenal contents and in some unavoidably swallowed saliva—all these factors modify any single determination. Only a sufficient number of individual examinations, interpreted statistically, can disclose the actual physiologic tendency.

The significance of this moderate increase of psychic secretion for the genesis of peptic ulcer is not obvious. The moderate acidity demonstrated here as the mean for the ulcer patient tends to corroborate the view of Majus and Porges (19) that appetite secretion is only secondary in importance to the gastric phase of secretion. The brief duration of the appetite secretion indicates that psychic factors are probably not concerned in the greater acid response to an Ewald meal exhibited by ulcer subjects from 1 hour to 1½ hours after ingestion. Chemical secretagogues appear more significant. Seemingly, appetite secretion is much less in quantity and in duration for man than for dog.

The results presented here may be explained in one of two ways. Either the "ulcer stomach" responds excessively to normal vagal stimuli reaching it during mastication or too many stimuli may be conveyed to it along the vagi during this process. This latter interpretation is consistent with the possible existence of vagotonia in peptic ulcer subjects.

SUMMARY

Appetite secretion was produced by "sham feeding" in a group of 35 normal healthy individuals and in a group of 34 patients with peptic ulcer of the duodenum.

During the first twenty minutes, after the mere chewing of an orange, the mean acidity of the group of ulcer patients was significantly higher than that of the group of normal persons. The higher level of appetite secretion in patients with peptic ulcer is similar to the response of this group to an Ewald meal.

The moderately higher acidity of appetite juice of ulcer patients does not warrant giving it a rôle in the genesis of peptic ulcer. Because of its variability, appetite secretion cannot be an aid in the diagnosis of duodenal ulcer.

Studies on Constitution and Peptic Ulcer

II. The Dermographic Time of Peptic Ulcer Patients and Normal Subjects*

By

H. NECHELES, M.D., Ph.D.
M. H. MASKIN, M.D.
and
J. MEYER, M.D.
CHICAGO, ILLINOIS

THE hypothesis that ulcer originates in vascular spasm of the stomach and the duodenum suggested that a general disturbance in vaso-motor tonus of ulcer patients might be detected in the type of skin response to stimulation, as expressed in dermographic reaction time. The term "dermographism," as used in this paper, denotes merely the appearance of a red streak upon the skin in response to stimulation.

An extensive literature on cutaneous vascular phenomena has been critically reviewed by Krogh (1) and Lewis (2), and will not be surveyed here. It would appear that capillariomotor function regulated as it is by an intricate nervous and humoral mechanism should constitute a sensitive indicator of some imbalance in the vasomotor system. Kraft-Ebing (3) has stressed

*From the Gastro-Intestinal Laboratory, Department of Physiology, Michael Reese Hospital, Chicago. Aided by the Louis L. Cohen Fund.
Submitted November 8, 1935.

the vasomotor lability of the nervous individual and described the skin writing and wheal formation which may occur. Moebius (4) has observed that hyperthyroid subjects blush easily; and Nothhaas (5) has suggested a relation between dermographic reaction time and basal metabolic rate.

MATERIAL AND METHOD

The subjects of this research were 80 patients with duodenal ulcer (64 males and 16 females); the diagnoses having been established by X-ray; and 62 normal individuals as controls (60 males and 2 females). The routine procedure consisted in exposing the intrascapular region for 30 minutes so as to acclimatize the skin to room temperature, then stroking the skin between the medial border of the scapula and the lateral edge of the vertebral transverse processes, and timing the appearance of the red streak. Russetski (6) has indicated that the skin of the chest and back reacts most intensively to given stimulation.

The instrument used in this operation, devised by Nothhaas (5) consists of two parallel bars supporting a vertical rider which moves between them, and which by means of an inner regulatable spring can be made to impinge upon the skin at a measurable and constant pressure (115 grams). Four readings of skin reaction-time were taken on each subject, and in many instances, duplicate readings were taken on subsequent occasions; these checked closely in most instances. The formulae of Fisher (7) were employed in the statistical treatment of the results presented below.

RESULTS

A significant difference between normal and ulcer subjects occurs if comparison is made between the entire ulcer and normal groups, irrespective of varying age distribution in both populations. The dermographic time for ulcer and normal subjects was 12.8 and 10.6 seconds respectively.

If, however, age groups are compared, no significant difference in dermographic reaction-time is evident between normal individuals and ulcer patients of similar age.

This disappearance of a difference in reaction-time, upon subdividing both groups into age categories, demonstrated that age represents an important factor in dermographism. Being identical in reaction-time, both groups, normal and ulcer were united, subdivided into age groups, which were compared statistically with one another. Here it became evident that a marked increase in dermographic reaction-time occurs with advancing age.

The results in Table I indicate clearly that the most rapid skin reaction occurs below thirty years of age (9.8 seconds); that the skin reaction is considerably retarded above this age; and that no significant difference obtains between the middle age group of 31-50 years (13.4 seconds) and the older age group of 51-70 years (15.4 seconds).

In no instance, and this includes the ulcer series, was wheal formation observed. There was no significant difference between sexes and no correlation between blood pressure and dermographic reaction-time. It may be noted here that, with few exceptions, all ulcer patients had low or normal blood pressures.

The identity of skin response in ulcer and normal subjects seems contradictory to the theory of von Bergmann (8) and others (9) that peptic ulcer is the resultant of a neuro-spastic tendency, as well as being inconsistent with the findings of Müller (10) that the arterioles, capillaries and venules in the skin, lips and stomach of ulcer subjects are tortuous, irregular and varicosed. It may be, of course, that the method employed here is inadequate for detection of the spasticity that may actually characterize the blood vessels of the ulcer subject, although it appears improbable that

TABLE I

Dermographic Reaction Time

Group	Age in years	No. of Subjects	Dermogr. Reaction-Time Means and Standard Error (Secs.)
A	12-30	45	9.8 ± 0.47
B	31-50	64	13.375 ± 0.724
C	51-70	33	15.424 ± 0.949

Difference of Means

Age Group	Difference of Means and Standard Error
B-A	3.575 ± 0.874
C-A	5.626 ± 0.972
C-B	1.952 ± 1.01157

a marked tonus of the capillaries would not alter the dermographic response in some manner.

The significance of the delayed capillary dilatation in the older age group still remains for speculation. Fundamentally it indicates a difference in capillary reactivity between older and younger individuals. Apparently the capillaries of an individual about 30 years of age require a longer interval for dilatation to develop in response to stimulation. Conceivably this might result from either a preponderance of the sympathetic-pituitary-adrenal constricting mechanism, or a deficiency of the antidromic-histamine dilating mechanism.

The experimental results of this paper may offer a partial explanation for the greater incidence of peptic ulcer above about 30 years of age, but they do not actually conform with the von Bergmann (8) theory of a general vasomotor disturbance in ulcer patients.

SUMMARY

No difference in dermographic reaction-time was found between a group of 80 ulcer patients and a group of 62 normal subjects.

There is a distinct relation between dermographic reaction-time and age. Until 30 years of age, derma-

graphic reaction-time is relatively short (9.8 seconds). Above this age, it slows down abruptly (13.4 seconds for the age group of 31-50 years) and then remains relatively constant (15.4 seconds for the age group of 51-70 years). This signifies an alteration with age of the capillaries of the skin and therefore, probably, of the skin itself.

The possibility of a correlation between incidence of peptic ulcer and changes in dermographic reaction time with age is discussed.

SECTION II—*Experimental Physiology*

A Study of the Effect of Anoxemia on the Pyloric Sphincter in Unanesthetized Dogs*

By

E. J. VAN LIERE, Ph.D., M.D.

and

J. E. THOMAS, M.D.

MORGANTOWN, WEST VIRGINIA

and

PHILADELPHIA, PENNSYLVANIA

IN 1933 it was reported that anoxemia caused a delay in the emptying time of the stomach in normal dogs (1). In a subsequent paper (2) it was shown that the effect of anoxemia on the pyloric sphincter of barbitalized dogs was inconstant. Further work was attempted on the mechanism of delay in gastric emptying time caused by anoxemia. This work (3) indicated that the delay at low degrees of anoxemia was at least partially caused by a pylorospasm, probably of a vagospastic nature, while the greater delay encountered at the higher degrees of anoxemia probably involved the added factor of a direct depression of the gastric musculature by the anoxemia.

In view of these findings it was thought well worth while to make a study of the effect of anoxemia on the pyloric sphincter in unanesthetized animals.

METHODS

Two previously operated dogs were used in this experiment. These animals each had two abdominal fistulae, one opening into the proximal part of the duodenum, and the other opening into the stomach. A rubber tube was placed in each of these openings, the two tubes being connected by a collapsible section at the pylorus and attached to a pressure tonometer and recording device as described in 1929 (4). It was thus possible to make simultaneous, synchronized tracings of the tone and the contractions of both the pyloric sphincter and the pyloric antrum.

Anoxemia was produced by allowing the animals to breathe from a rubber bag, connected with an apparatus previously described (5) for mixing oxygen and nitrogen in the desired proportions. A flutter valve was inserted in the otherwise closed system, allowing the animal to expire to the outside, thus preventing the accumulation of carbon dioxide.

During the control periods the animals were allowed to breathe a gas mixture containing 20% of oxygen. Anoxemia was administered by reducing the oxygen to the desired percentage without changing the total pressure within the system. The oxygen percentages used in this experiment were: 6%, 9%, and 14%, respectively.

Attention was, of course, given to all mechanical and other details essential to accurately controlled anoxemia, and to uniform experimental conditions.

RESULTS

For convenience in presentation, the results obtained will be given in sections, according to the degree of anoxemia.

6% OXYGEN

Seven determinations were made upon the pyloric sphincter at this oxygen percentage, corresponding to

*From the Departments of Physiology of West Virginia University and of the Jefferson Medical College of Philadelphia.
Submitted September 23, 1935.

an altitude of about 30,000 feet. Figure 1 shows a typical response. There was an immediate increase in the tonus, accompanied by an increase in the frequency of the contractions. After about 9 minutes the tone fell off toward normal, and the character of the contractions changed. The contractions became less frequent, but were quite vigorous and prolonged, approaching a condition of spasm. The contractions assumed their normal character only after the anoxemia had been discontinued for about 5 minutes.

The tone of the sphincter was increased in every one of the seven trials at this oxygen percentage, but in two cases the increase was delayed for about 3 minutes after administering the anoxemia. The vigor of the contractions was increased in 4 cases, and diminished in 3.

In every trial the tone of the antrum remained unchanged for about 5 minutes, then rose transiently, and fell to below its normal level. The contractions of the antrum also showed this delayed initial stimulation, with a subsequent depression to a subnormal level. In some instances the contractions were finally completely abolished.

9% OXYGEN

Figure 2 is typical of the results obtained using this degree of anoxemia, which corresponds to an altitude of about 22,000 feet. There was an immediate, marked rise in the tone of the sphincter, followed by a fall to nearly normal after 10 minutes. The height of the contractions of the sphincter was decreased, slightly at first, but still further, concurrent with the fall in tone.

The tone of the antrum fell immediately upon administering the anoxemia. The height of the contractions was at once diminished, and after 12 minutes the contractions practically disappeared.

Eight determinations were made at this percentage. In six cases the tone of the sphincter showed a rise, but this rise was delayed in one case. The height of the contractions of the sphincter was increased in 3 cases, decreased in 4, and unchanged in 1.

About half the determinations on the antrum at this degree of anoxemia showed an immediate fall in tone and contractions, with an abolition of the contractions after about 10 minutes. The other half showed an initial stimulation of both the tone and the contractions, with a subsequent fall of both to below their previous normal level.

14% OXYGEN

This mild degree of anoxemia was administered in two cases, in an attempt to establish a threshold. This oxygen percentage corresponds to an altitude of only about 10,000 feet. Figure 3 is a section of one of the records obtained. The tone of the sphincter remained unchanged for about 3 minutes, and then rose for about an equal period. Concurrent with the rise in tone the frequency of the contractions was increased, and they became more spastic in nature. At the end of 6 minutes the record assumed a normal character.

In the other trial at this oxygen percentage the tone of the sphincter was unchanged, but the vigor of the contractions was increased considerably.

No determinations were made upon the antrum at this degree of anoxemia.

RESUME

Using 6%, 9%, and 14% oxygen, respectively, it was found that the tone of the pyloric sphincter was increased in 14 of 17 trials. The vigor of the contractions of the sphincter was increased in 8 cases, decreased in 8, and unchanged in 1. The antrum showed, in about half the cases, an initial stimulation of tone and contractions, followed by a depression to a subnormal phase. In the other half of the cases the tone and the contractions were initially decreased, and later the contractions were abolished.

DISCUSSION

In the light of previous findings (2) it seems rather surprising that such constant results were obtained on the tone of the sphincter. However, this previous work showed that in the majority of animals anoxemia produced a rise in the tone of the sphincter, and that as a rule, consistent results were obtained with each animal. Since a small number of animals was used in the current experiment it is not so remarkable that a rise in the tone of the sphincter was obtained in 14 of 17 trials. Any increase in pyloric tone, not accompanied by a corresponding increase in the tone of the gastric muscle as a whole, must be considered as a potential factor in delaying gastric emptying. In anoxemia the tone of the gastric muscle tends to be decreased; consequently the increase in pyloric tonus, when it occurs, may be a significant factor in the mechanism of delayed gastric emptying time.

It is interesting to note the inconstancy of the effect of anoxemia on the contractions of the sphincter. In 8 cases they were increased in vigor, in 8 cases they were diminished, and in 1 case they were unchanged. In general, it seemed that if the sphincter was contracting vigorously its contractions would be diminished, and vice versa, so that the effect of the anoxemia seemed to depend upon the previous state of the sphincter.

We realize that 6% and even 9% oxygen represents a rather severe degree of anoxemia. These percentages were used for the sake of ease in interpreting the records, as well as to check on the findings of previous work in which similar percentages were used.

An important part of the present work lies in the fact that significant changes, in both the tone and the contractions of the pyloric sphincter were produced by 14% oxygen. This is a mild degree of anoxemia, corresponding to only about 10,000 feet altitude. In a previous paper (2) it was reported that the threshold for this effect of anoxemia in barbitalized dogs was about 9% or 10% oxygen, and was suggested that a lower threshold might be obtained in unanesthetized animals. The threshold of 14%, herein reported, checks rather closely with the threshold of 15.5% oxygen reported in previous work on gastric emptying time in unanesthetized dogs (1).

It must be noted that anoxemia produces a distinct effect on the pyloric antrum. 6% oxygen caused, after a slight delay, a rise in the tone of the antrum, with a concurrent rise in the height of the contractions. In all these cases the antral contractions were later diminished, and in some instances they disappeared altogether. In attempting to explain the mechanism of the delay in gastric emptying time in anoxemia it has been previously reported (3) that high degrees of anoxemia directly depress the gastric musculature. The findings reported here are in accord with this view.

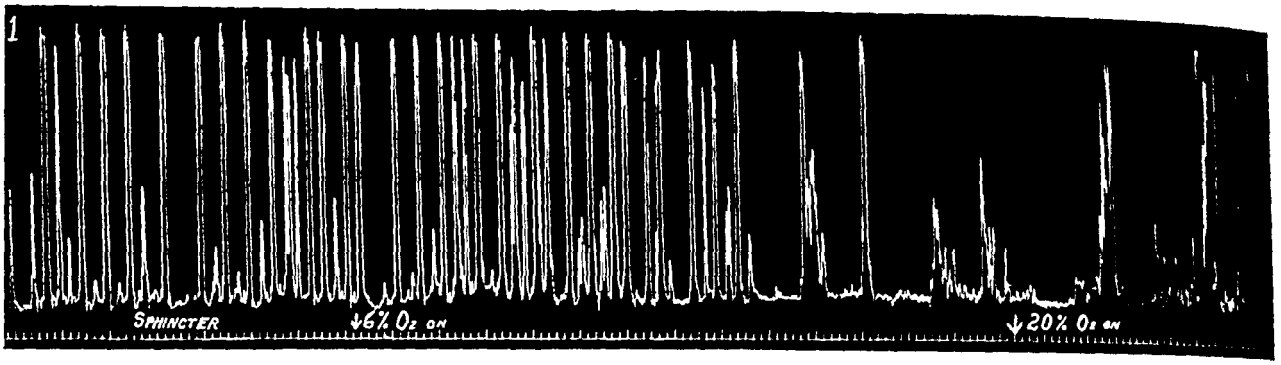

Fig. 1

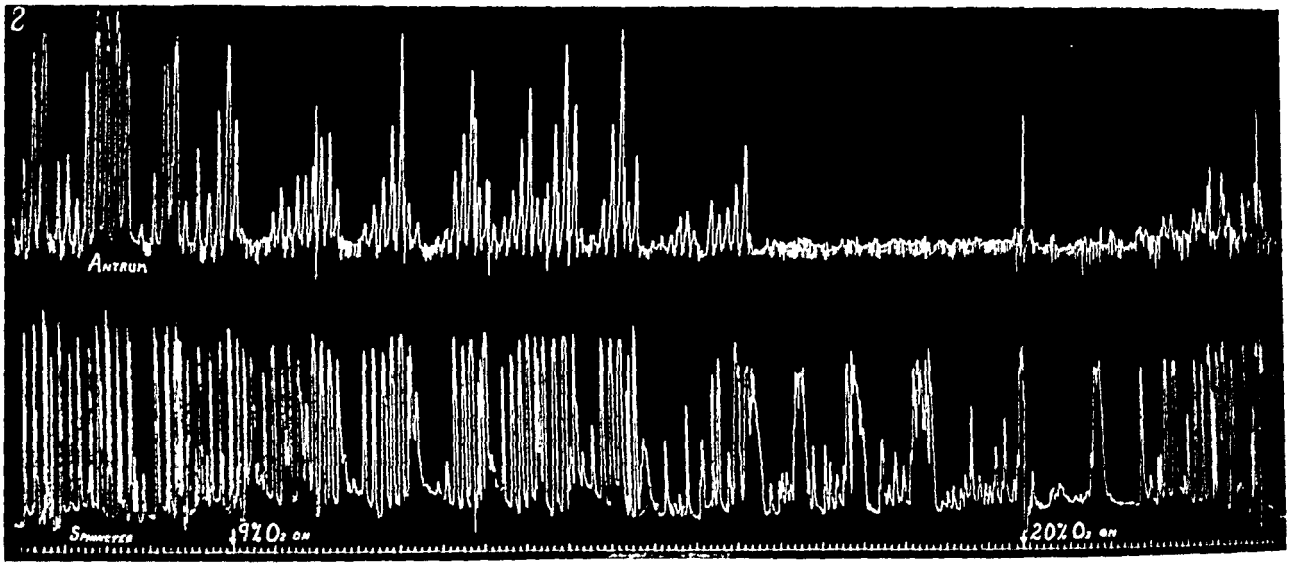

Fig. 2

Fig. 3

Previous reports have further indicated that the pylorospasm produced by anoxemia was on a vagospastic basis (3). The present work would seem to confirm this finding, in so far as certain cases of increased pyloric tonus were accompanied by an initial increase in the motility of the antral musculature. It must be remembered, however, that severe anoxemia, while sometimes transiently increasing antral contractions always decreased antral tone, and ultimately decreased the motility.

It is recognized that there is an increased secretion of epinephrine during anoxemia, probably associated with a general splanchnic stimulation. If so, in view of the vagospasm indicated in previous work, we may in anoxemia be dealing with generalized autonomic excitation. Although the results of such excitation are unpredictable, they could readily include, among other things, such phenomena as we have encountered. In particular, some of the delayed effects on the pylorus could be due to increased adrenal activity. It would be of interest to repeat these experiments on adrenalectomized animals.

It is possible that some of the objective findings of the work here reported may be explained on other bases than those used above. However, in view of the close correlation which seems to exist between this work and previous work mentioned in this paper, the views set forth in this discussion are presented as working hypotheses.

SUMMARY AND CONCLUSIONS

In two unanesthetized animals with permanent fistulae, it was found that anoxemia produced a rise in the tone of the pyloric sphincter in 14 of 17 trials. Reasons are given for including this factor in the mechanism of delayed gastric emptying time during anoxemia. The threshold for this increase in tone was about 14% oxygen. This corresponds to an altitude of about 10,000 feet, and is a rather mild degree of anoxemia.

The change in pyloric contractions was less constant. These were increased in vigor in about half the trials, and decreased in the other half. In general, it seemed that vigorous normal contractions were diminished by anoxemia, and vice versa.

The anoxemia decreased the tone of the pyloric antrum, but in some cases caused an initial increase in the vigor of its contractions. However, these increased contractions were later diminished to below their previous normal level. In most cases the vigor of the contractions was immediately decreased, and the contractions later abolished.

We feel it is possible that these factors, when combined, may be sufficient to account for the delayed gastric emptying seen in anoxemia. Whether or not the pylorus functions as a regulator of gastric emptying under normal circumstances, this work indicates that it may do so under special conditions such as anoxemia. The exact mechanism of the increase in pyloric tonus in anoxemia remains obscure; its further elucidation should shed light on the complex control of the pylorus.

Studies of Pepsin in Human Gastric Juice*

IV. The Influence of Gastric and Duodenal Disease**

By

FRANCIS R. VANZANT, M.D.***
ARNOLD E. OSTERBERG, Ph.D.†
WALTER C. ALVAREZ, M.D.‡
and
ANDREW B. RIVERS, M.D.‡
ROCHESTER, MINNESOTA

IN the third paper of this series of five (1), we reported studies of the physiologic aspects of secretion of pepsin and gave details as to technic, best method of obtaining juice for study, range of normal values, means and medians, coefficients of variation, effects of age and sex, and so forth.

In this paper we report concentrations of pepsin observed in gastric juice obtained from 1472 men and 374 women, affected with several types of gastric and duodenal disease. We studied also the effects on the secretion of pepsin exerted by successful and unsuccessful operations on the stomachs of 528 persons. The work was done to see if determinations of pepsin in gastric juice are likely to be of any help in the diagnosis of disease.

TECHNIC

For details as to methods used the reader is referred to papers I (2) and III (1) of this series. Suffice it to say

*Studies I and II of this series bore the general title, "Studies of Gastric Pepsin."
**This work was aided by a grant from the Josiah Macy, Jr., Foundation.

Submitted September 16, 1935.

here that we have used Osterberg's modification of the Gates-Gilman-Cowgill method for measuring pepsin. The unit of pepsin used represents the proteolytic activity of a 1 per cent solution of a 1:10,000 commercial pepsin. We used three types of juice which for the sake of brevity we will call test-meal, fasting, and histamine juice. The first was obtained one hour after the ingestion of eight arrowroot cookies and 400 c.c. of water, the second was removed in the morning before breakfast, and the third was removed in six samples taken at intervals of ten minutes following the injection of a dose of histamine representing 0.1 mg. for each 10 kg. of body weight. A small-bore Sawyer tube was used.

With the first two types of juice we estimated concentrations of pepsin. With histamine juice we obtained also a figure representing quantity of pepsin which we call PV or pepsin-concentration times volume of juice secreted. The particular PV referred to in several places in this paper represents the sum of the quantities of pepsin secreted in each of the first three ten-minute intervals after the injection of the histamine. Studies of the coefficients of variation for secretion of pepsin in the three different types of juice showed that figures representing concentration of pepsin in test meal juice were the least variable and probably therefore the best to use in studies such as the one here reported.

In order to simplify the reporting of all data for pepsin obtained with the three types of juice taken from a group of persons with some particular disease, we have converted figures for concentration of pepsin in fasting juice and for quantity of pepsin secreted in the first thirty minutes after injecting histamine into figures for concentration in test-meal juice, by multiplying by factors of 0.63 and 0.35 respectively. The derivation of these factors was described in paper III of this series (1). We felt safe in combining data in this way not only because we found the numerical relationships between pepsin values in the different juices so constant but because before making Table I, with the combined index, we first studied median and mean values for the three juices separately, and found that, within limits of error of sampling, they were affected in the same way by each disease.

We have depended on the median rather than the mean as an index of central tendency because of the skewness of the distributions. Details in regard to this will be found in paper III (1).

Figures for men and women were so different that they had to be studied separately. We have not attempted to correct the figures for the factor of age. Fortunately, in most of the groups the mean age was about the same.

SECRETION OF PEPSIN IN DISEASE

Duodenal ulcer. As everyone knows, duodenal ulceration is a disease that varies markedly in its severity. Accordingly, we divided our cases, first, into two groups of the quiescent or healed, and the active; and second, the active cases were subdivided into the medical and the surgical depending on the type of treatment advised by the physicians and surgeons who saw the patient. This criterion was used because in most cases this decision as to the type of treatment advisable is based on the severity of the symptoms or the presence of complications.

TABLE I

Concentrations of Pepsin and Acid in Gastric and Duodenal Diseases

*Incidence of achlorhydria in per cent and figures for mean acid are for cases in which test meal was used.
†Figures for pepsin are derived from analyses of test meal, histamine and fasting juice. Values obtained from study of fasting and histamine juice were converted into terms of pepsin in test-meal juice as explained in the text.

Table I shows that the median value, expressed in terms of concentration of pepsin in test-meal juice, rose definitely with the severity of the disease. In the case of men, the three medians of 252, 352, and 501 are to be compared with the median of 148 for normal persons. In the case of women, the corresponding figures were 188, 209, 272, and, for the normal, 126. It is of interest to note that free acidity varied in the same way as did the pepsin, the mean values for healed, medical and surgical ulcers in men being 49, 54, and 60 respectively, as compared with a normal of 44. For women, the corresponding figures for acid were 42, 47, 51, and 35.

In the case of many of the patients with duodenal ulcer who were operated on, the surgeon described the lesion as being acutely inflamed, multiple, or penetrating, or complicated by the presence of duodenitis, gastritis, or a gastric ulcer. On studying the concentra-

tions of pepsin in cases classified under these headings, we found a number of interesting things. For instance, median concentrations of pepsin in cases of duodenal ulcer complicated by gastric ulcer or gastritis were decidedly lower than in cases of simple duodenal ulcer. As will be seen in the next section the median concentration of pepsin in cases of gastric ulcer was only slightly above normal. A possible explanation of this is that inflammation of the gastric mucosa apparently tends to lower the secretion of pepsin and acid, which otherwise might be high. When duodenal ulcer was complicated by duodenitis, the median concentration of pepsin was approximately the same as that observed in the case of the whole group of surgical duodenal ulcers, and in the cases of penetrating and of multiple duodenal ulcers. In patients in whom the ulcer was producing obstruction, there was a high median value of 583 units.

The acuteness of the inflammatory process was reflected in the levels of concentration of pepsin; in those cases in which the ulcer was described as being acutely inflamed the median was 903 units whereas in those in which it was said to be subacutely inflamed, it was 514 units, and in those with a more chronic type of ulcer it was only 483 units.

Curiously in the case of 112 patients who had had one or more hemorrhages and in a group of twenty-six who had suffered with intractable symptoms, the median concentration of pepsin was only 375 units.

Pseudo-ulcer. We use the term "pseudo-ulcer" to describe a syndrome resembling ulcer in patients in whom an ulcer cannot be demonstrated. The patients usually show the same tense, sensitive, nervous make-up which is seen so commonly in persons with true ulcer.

Table I shows that the figure for median concentration of pepsin in men was 405, which lies between those for medical and surgical ulcers. The mean acidity of 52 lies between values for healed and medical ulcers. In our series of twenty women, it is curious that the median figure for pepsin was the same as that of the median of the normal controls; the mean acidity was eight points above normal, corresponding to that for healed ulcers.

It is obvious from this that estimations of the concentrations of pepsin and acid are equally useless to the clinician, who, in these puzzling cases, has to decide whether or not an ulcer is present.

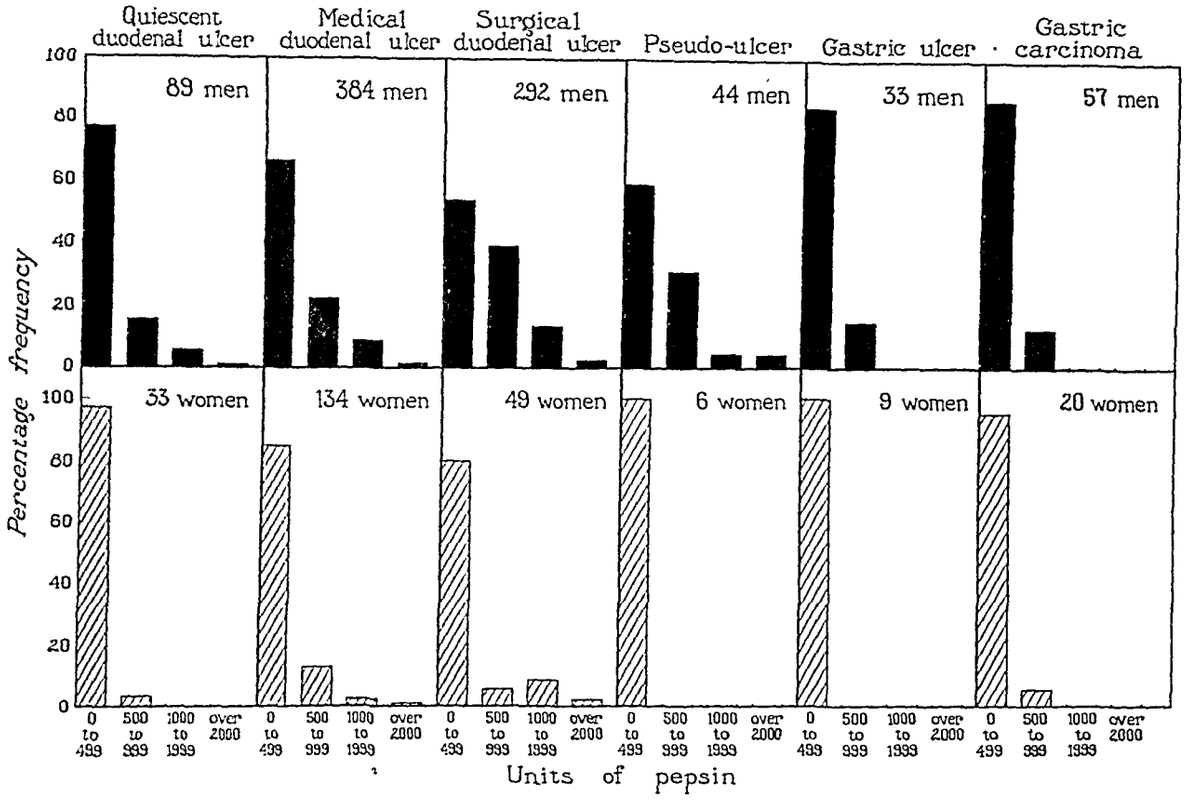

Fig. 1. Percentage distributions of concentrations of pepsin in test-meal juice obtained from men and women with different gastric and duodenal diseases.

Gastric ulcer. In men with gastric ulcer the median concentration of pepsin was 253 units which corresponds with that of healed duodenal ulcer. The mean acidity in this group of seventy-five was that of normal persons. As we have shown in a paper based on the analysis of data from a much larger group of patients, the acidity is usually somewhat reduced below the level of normal.

In a group of twenty-one women with gastric ulcer the median pepsin was about normal and the mean acid was seven points above normal.

Carcinoma of the stomach. The reader must be warned at this point that since, in the case of carcinoma of the stomach, we were most concerned with the problem of diagnosis, which is seldom difficult except when the lesion is small and ulcer-like, most of the persons selected for study were of the type who have considerable free acid in the gastric juice. Sixty-seven per cent of the men and 60 per cent of the women had such free acid, and the respective means for data from these men and women were 33 and 36 units.

It is interesting to note that the men with carcinoma showed a median concentration of pepsin of 276 units which is to be compared with 253 for benign gastric ulcer and 252 for healed duodenal ulcer. In women

the median pepsin was 127 which is almost identical with the normal of 126.

Obviously then, estimations of pepsin cannot contribute anything to the oftentimes difficult problem of differentiating carcinomatous and benign gastric lesions.

The stomach that has been operated upon. It is generally conceded today that a successful gastro-enterostomy lowers gastric acidity. Now we find that in seventy men who returned to report satisfactory results after this operation, the median pepsin value was 126. If we assume that, before operation, these patients had a median pepsin of about 500, such as we find in the cases of Mayo Clinic patients with surgical duodenal ulcer, then we must conclude that the operation reduced the concentration of pepsin to a fourth of its former value, while, at the same time, it reduced the acidity to two-thirds of its presumable former value.

Curiously, in our series of seventeen women with a successful gastro-enterostomy, the figure for median pepsin was only 34 units lower than that for women with surgical ulcer. Still more curious is the fact that in the case of twenty-four women with recurrent ulcer after gastro-enterostomy, the median pepsin value was 136, which is closer to the normal of 126 than to the 272 for surgical ulcer, but with such a small group it is impossible to say whether or not this low figure has any significance.

In the case of 207 men who had submitted to gastro-enterostomy and who returned with symptoms of ulcer, the median pepsin value was 212, which is to be compared with the 126 for a group of patients with successful gastro-enterostomy and the 501 for patients with surgical duodenal ulcer.

Evidently, in the presence of an active ulcer after gastro-enterostomy, the secretion of pepsin is increased much as is the secretion of acid.

There were forty-eight men and nine women who returned after a successful operation on the stomach other than gastro-enterostomy. In most cases this was a pyloroplasty. In men the median pepsin value was practically the same as that seen in cases of successful gastro-enterostomy but in women it was 25 per cent higher.

In the case of the 140 men with unhealed or recurrent ulcer after some gastric operation, other than gastro-enterostomy, the median pepsin value was 414, which is to be compared with the 130 for patients with similar but successful gastric operations and the 212 for patients with an unsatisfactory gastro-enterostomy.

In the case of thirteen women with unsuccessful gastric operations, other than gastro-enterostomy, we found the presence of an ulcer associated with lower concentrations of pepsin. The median of 239 units is to be compared with the 298 units for women with a successful gastric operation other than gastro-enterostomy, and the 136 units for women with an unsuccessful gastro-enterostomy.

Figure 1 shows percentage distributions of concentrations of pepsin in test-meal juice obtained from men and women with the commoner types of gastric and duodenal disease.

CONCLUSIONS

It is obvious from the figures in Table I that the median concentration of pepsin in gastric juice was closely correlated with the severity of the symptoms produced by ulceration in duodenum or stomach. Unfortunately for the clinician, there was so much individual variation in the figures and so much overlapping of distributions representing data from normal calm persons, from highly nervous persons, and from patients with the several diseases, that it is not likely that an estimation of the concentration of pepsin can ever have much diagnostic value. The test fails the physician just where he most needs help, namely in differentiating pseudo-ulcer from duodenal ulcer and malignant from benign gastric ulcer.

In the next paper we shall take up the possible value of determinations of pepsin in detecting the patient with ulcer who is likely to do badly after an operation on the stomach.

SUMMARY

Studies were made of concentrations of pepsin found in the gastric juice of 1937 men and 437 women suffering with several types of gastric and duodenal disease, with or without the modifying influence of a successful or an unsuccessful operation on the stomach.

Concentrations of pepsin were estimated by a modification of the Gates-Gilman-Cowgill method. The median was used as a measure of central tendency.

In cases of duodenal ulcer the concentration of pepsin was considerably higher than normal, and it varied with the severity of the symptoms of the disease and with the degree of acuteness of the inflammatory process.

There was a similar gradation in the acidity of gastric juice obtained from patients with the different types of ulcer but the differences were not so great.

In cases of pseudo-ulcer in men the median pepsin value lay between the figures for cases of medical and surgical duodenal ulcer. In women with pseudo-ulcer the median pepsin did not differ from that of normal controls.

In men with gastric ulcer the median pepsin value was slightly increased; in women it was practically that of the normal controls.

In the case of carcinoma of the stomach data were taken mainly from patients with small lesions and free hydrochloric acid in the gastric juice. In the men the concentration of pepsin was slightly increased to a level about that seen with benign gastric ulcer; in the women there was no change from normal.

In the case of men in whom a gastro-enterostomy had been successful, median concentration of pepsin was normal, which means probably that there had been a drop of about 375 units from the high median value found in patients with surgical ulcer. This drop of 75 per cent is greater than the 34 per cent drop observed in gastric acidity.

In the presence of a recurrent duodenal ulcer or of a jejunal ulcer following gastro-enterostomy, the concentration of pepsin appeared to be increased.

The same type of change was observed when ulceration followed other types of operation on the stomach

or duodenum. In women the groups studied after operations were so small that no positive conclusions could be drawn as to the slight changes observed in the median concentration of pepsin.

Unfortunately the individual variability in pepsin readings is so large, and the overlapping of distributions so great, that estimations of this ferment can seldom have much diagnostic value.

Studies of Pepsin in Human Gastric Juice*

V. Its Prognostic Value**

IF only the gastro-enterologist could tell in advance which of his patients with ulcer, if sent for surgical treatment, would promptly get well and stay well, and which would soon return with the lesion reactivated or with a new one boring into the jejunum, his life would be much happier, and no longer would he let a small percentage of very bad results restrain him from making use of an operation which, in most cases, works perfectly.

Under the compulsion of this fear, every clinician and surgeon of experience has developed a set of "hunches" which cause him to refuse operation to certain patients, usually the tense, nervous ones with a high gastric acidity. But how many practitioners have taken the time to record their prophecies and then, later, to compare them with what actually happened? Or how many have correlated the degree of gastric acidity found at the time of the first examination with the results obtained after operation?

Because previous studies at this Clinic (1) had shown that there is nothing distinctive about the gastric acidities of the patients who do badly after gastric operations, we were particularly desirous of seeing if analyses of another component of gastric juice, in this case pepsin, would have any better prognostic value. We here report work done to see if there is any correlation between the concentration of pepsin in the gastric juice and the character of the results obtained after operation on the stomach.

TECHNIC

In estimating concentrations of pepsin, we used a modification of the Gilman-Cowgill method, details of which can be found in a paper by Osterberg, Vanzant, and Alvarez, published in 1933 (2). In most cases we used gastric juice withdrawn one hour after the giving of a test meal consisting of eight arrowroot crackers and 400 c.c. of water. When fasting or histamine juice was used, the figures expressing concentration or amount of pepsin were converted into terms of concentration of pepsin in test-meal juice, with the help of factors given in paper III of this series (3). The median was used instead of the mean as an index of central tendency. The figures for concentration of pepsin for men and women were so different that we studied them separately.

RESULTS

In preparing for the analysis here reported we began a few years ago to study cases in which the concentration of pepsin in the gastric juice was known and in which the patient, after an operation on the stomach, returned to this Clinic with recurrent symptoms of ulcer. When we began to write this paper, we had data from thirty-eight such cases in which a diagnosis of "recurrence" had been made after study here. In order to secure data from a control group of persons who had had, first, the necessary study of the gastric juice, second, an operation on the stomach, and third, a good result, we sent out a questionnaire which brought in 238 replies. These answers were segregated into three groups denominated "entirely satisfactory," "slight indigestion," and "possible recurrence."

All the data analyzed in this paper were from patients with duodenal ulcer; we did not find any case of recurrence following operations for the relief of gastric ulcer or combined gastric and duodenal ulcer. Altogether we had data from 233 men and forty-three women. In 162 cases, the operation performed was gastro-enterostomy; in ninety-two, it was pyloroplasty; in twenty-one, it was resection, and in one case, it was a simple excision of the ulcer.

On examining the data we found that, in the case of the 147 men who secured a perfect result, the median pepsin concentration, before operation, was 433 units. This figure stands halfway between the median of 352 for cases of "medical" ulcer and the

9213

median of 501 for cases of "surgical" ulcer, reported by us in paper IV of this series (4). The men who were suffering with symptoms which suggested the presence of a recurrent or new ulceration were found originally to have had a median concentration of 467 units of pepsin, while those men in whose case a definite diagnosis of recurrent or new ulceration was made, had originally a median concentration of 485 units.

Even if we could be sure that these small differences in the median would be maintained if we were to study thousands of cases, the differences are so small and the overlapping of distributions is so great that we must conclude that the concentration of pepsin in an individual must be without prognostic value. Incidentally, it should be noted that in each group the median value was less than 500 units which marks the upper limit of normal.

In the case of the women, the groups were so small that little can be inferred from the differences observed in the median values for pepsin. Curiously, the highest concentrations of pepsin were found in patients who obtained the best results, and the lowest in patients who suffered a recurrence.

CONCLUSIONS

It is obvious from this work that measurements of concentration of pepsin in the gastric juice have no prognostic value.

The Effects on the Gastric Juice of Man of Six Weeks' Deprivation of Vitamin B_1*

By

WALTER C. ALVAREZ, M.D.**

and
ARNOLD E. OSTERBERG, Ph.D.§
ROCHESTER, MINNESOTA

SEVERAL years ago, Danysz-Michel and Koskowski (1922) (1) and Farnum (1926) (2) reported a falling off in gastric secretion in animals placed on a diet poor in vitamin B_1. Gildea, Kattwinkel, and Castle (1930) (3), using a similar diet, did not see much change in gastric acidity, and Cowgill and Gilman (1934) (4) had some negative results, but Webster and Armour (1934) (5) and Komarov (1934) (6) reported that the stomachs of their dogs regularly became anacid. This happened usually after the animals had been on the deficient diet for about three weeks, and the gastric mucosa returned to normal within a few days after a complete ration was again supplied.

These results of Webster and Armour and Komarov were so striking that the senior writer of this paper decided that the experiment should be repeated on men and women. Obviously, if this type of dietary deficiency were promptly to produce anacidity in man, the medical profession might find itself in possession of a convenient method of treatment for intractable ulcer. Fortunately for our purpose, experimenters seemed to agree that lack of vitamins other than B_1 had no effect on gastric juice.

Against the hope that food deficient in B_1 might be helpful in cases of ulcer was the fact, reported by several observers (Sure and Thatcher, in 1934 (7), and Dalldorf and Kellogg in 1932 (8)), that such a diet sometimes seems to produce peptic ulcer in rats. Actually, Sure and Thatcher recommended that attempts be made to treat ulcer with a diet rich in vitamin B_1.

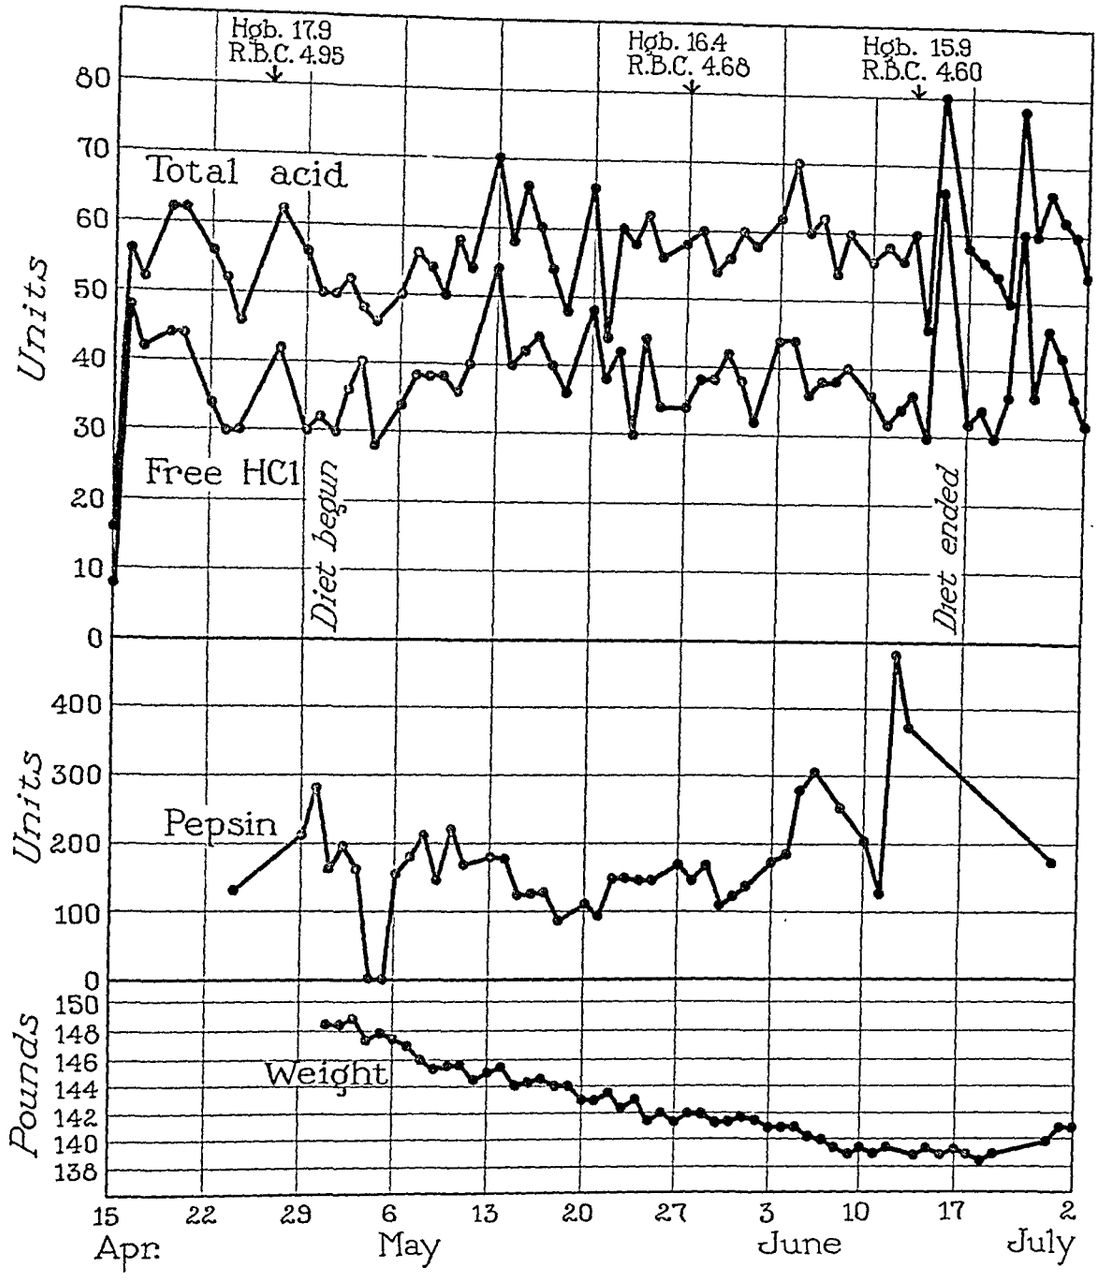

Fig. 1. (Dr. P.). Curves showing daily changes in concentrations of acid and pepsin in the gastric juice, and changes in weight.

After reviewing these contradictory reports of experiments on animals, we turned to the literature on beriberi to see if patients with this disease suffer with anacidity, and again we were puzzled. Kitamura and Shimazono (1912) (9) studied the gastric juice of eighty-seven Japanese soldiers with beriberi and found only about a third with anacidity and subacidity. In most of these cases the disease was severe. Ohta and Izumita (1930) (10) studied children with beriberi and found most of them with an anacid or subacid stomach; a few had normal acidity, and a very few, hyperacidity. Contrary to the experience of the experimenters with dogs, the Japanese physicians found that in the children, gastric acidity returned to normal only after three months of treatment.

In Vedder's monograph (11) on beriberi, we did not find any reference to the incidence of peptic ulcer in patients with this disease, but in a review by Cowgill (1934) (12), we found that Middleton (1914) (13) reported a case of duodenal ulcer complicating beriberi. We haven't access to this paper so we do not know if the beriberi resulted from the use of too restricted a diet in the treatment of ulcer. Sixty-five per cent of Kitamura and Shimazono's sick soldiers were without symptoms of indigestion.

As we were starting our experiment we found the articles by Elsom (1935) (14), who kept two persons for five months on a diet moderately deficient in vitamin B_1. It should be noted that the two persons studied by Elsom were chosen because they had already shown symptoms suggesting the presence of beriberi. In one case, gastric acidity was normal when tested at the end of the period of dietary restriction, and in the other, acid could be obtained only after injecting histamine.

On April 15, 1935, after consultation with G. R. Cowgill and R. M. Wilder, we began the experiment here reported with three volunteers. *Dr. P.*, a man, twenty-nine years of age, was 174 cm. (5 feet 9 inches) in height, and weighed 67.5 kg. (148.5 pounds). His basal metabolic rate (the mean of four tests) was —10% and his ideal weight 69 kg. *Mrs. P.*, twenty-seven years of age, was 169 cm. (5 feet 7 inches) in height, and weighed 50 kg. (110 pounds). Her basal metabolic rate (the mean of four tests) was -7%, and her ideal weight was 63 kg. *Miss S.*, aged forty-five

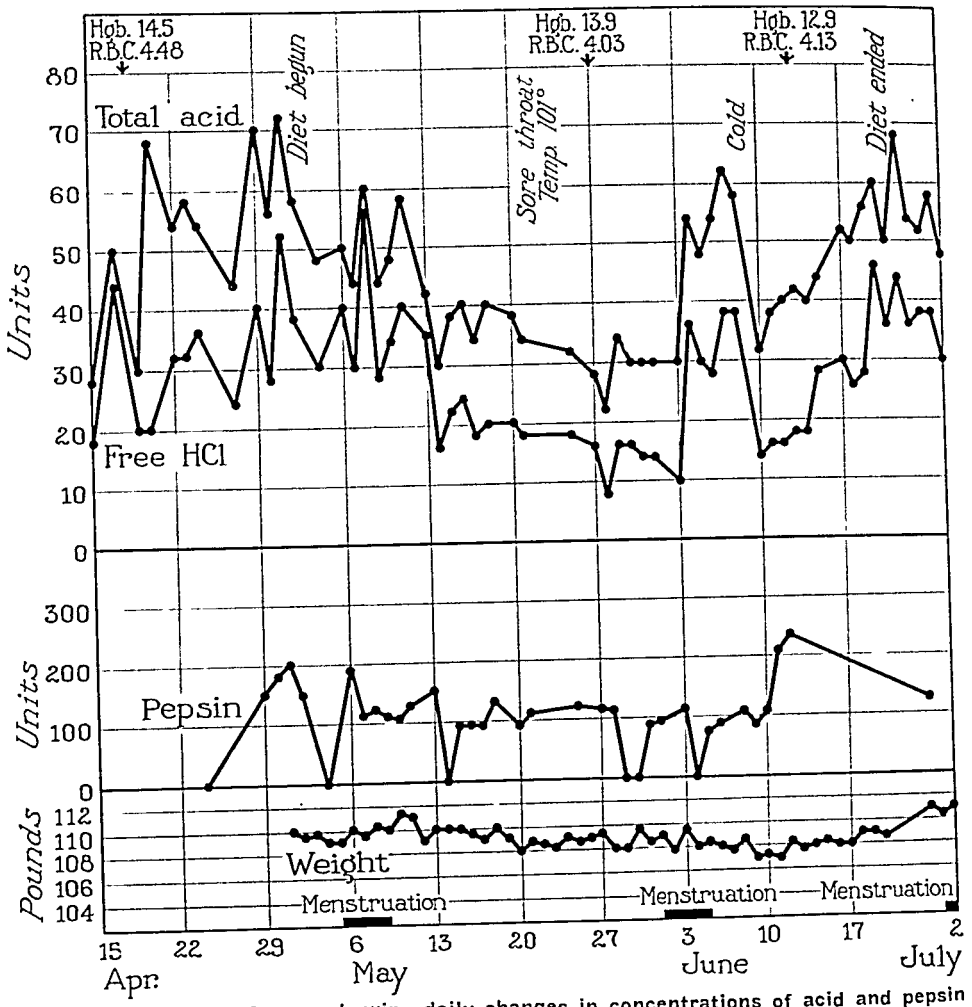

Fig. 2. (Mrs. P.). Curves showing daily changes in concentrations of acid and pepsin in the gastric juice, and changes in weight.

years, was 166 cm. (5 feet 5 inches) in height, and weighed 76 kg. (167.5 pounds). Her basal metabolic rate (average of three tests) was -21%, and her ideal weight was 66 kg. All were interested in medicine and could be depended on not to eat anything but what was prescribed. All three remained at work.

The first two have always enjoyed good health and good digestion; the third suffers with an ulcer-like syndrome but has no demonstrable ulcer in stomach or duodenum.

In prescribing the diet for these three persons we were guided by the standards given in Cowgill's splendid monograph (15) on the vitamin B requirement of man. From his chart number 6, we found that the minimal vitamin/calorie ratio for *Dr. P.* was about 1.85. *Mrs. P.'s* ratio for her actual weight was 1.40 and for her ideal weight, 1.80. *Miss S.'s* ratio for her actual weight was 2.15 and for her ideal weight, 1.85.

For the sake of convenience in calculating and handling the diet all three volunteers were given a diet which supplied 2200 calories and 2687 units of vitamin B_1. This gave a vitamin /calorie ratio of 1.2 which, if maintained for a sufficiently long period, should certainly have resulted in illness. Fortunately, beriberi does not appear until a deficient diet has been consumed for at least three months (Vedder, 1913) (11).

A gastric analysis was made almost every day. *Miss S.* was already well-used to the stomach tube, and the other two soon became accustomed to passing it themselves.

We used the usual test meal employed at The Mayo Clinic consisting of eight arrowroot cookies with 400 c.c. of water. The gastric juice was removed after one hour with the help of a small-caliber Sawyer tube. The acidity was titrated in the usual way with Töpfer's reagent and phenolphthalein. Pepsin was measured with a modification of the Gilman-Cowgill method described by Osterberg, Vanzant, and Alvarez (1933) (16).

The first two weeks of the experiment were spent in establishing base lines of gastric acidity and concentration of pepsin while the volunteers were on a liberal diet. On the first day of May, they began taking all their meals at the Rochester Diet Kitchen where the food, low in vitamin B content, was prepared. At each meal they ate all the food placed before them. The only complaint made came from the two persons who were restricted as to calories; naturally, they were hungry.

Figure 1 summarizes the results of the experiment on *Dr. P.* After the first day, when anxiety probably accounted for the marked subacidity observed, he was found to have a free acidity averaging about 35 units. Soon after he went on the deficient diet the acidity rose to a mean around 42 units, and later it dropped to

about 38 units. During most of the experiment, the concentration of pepsin varied around 150 units, which is normal.

Three days before the end of the experiment, *Dr. P.* was overjoyed to hear that he could soon eat freely again. He had been working hard, eating less than he wanted, losing weight, and suffering somewhat from hunger. Accordingly, when he saw relief on the way, his mind filled with thoughts of food, and he amused himself with plans of the meals he was going to order. Apparently as a result of this there came a sudden upward surge in the concentration of the pepsin in the gastric juice. It rose to a level of 480 units, which is about the upper limit of normal. Three days later, when he began to eat what he pleased, there came a second remarkable rise, this time in the free acid titer of the juice.

Dr. P. lost 9½ pounds (4.3 kg.) during the experiment, most of this being due to the caloric deficiency in the diet. He lost another ½ pound (0.2 kg.) during the five days following the cessation of the experiment, and then he gained 3 pounds (1.4 kg.) A month later, he had not gained any more of the lost weight, but this may have been due to the fact that he has seldom gained during the heat of summer.

Except for hunger, *Dr. P.* felt well throughout the period of the experiment. He felt tired during the last week, but this may have been due to overwork.

We cannot see any evidence from this experiment of a deleterious effect of the deficient diet on gastric acidity; if anything, the acidity was slightly raised. The concentration of pepsin in the gastric juice was also unaffected.

The record of *Mrs. P.* is very interesting (Fig. 2). She began with a free acidity of about 32 units, with limits of 20 and 52 units. On May 14, after she had been living on the deficient diet for two weeks, the free acidity fell suddenly to around 15 units, where it tended to remain. A week later, on May 21, much soreness of the throat appeared, with general malaise and a temperature of 101° F. She was in bed three days but kept to the diet. The free acidity continued to fall and, on May 28, it was only 8 units. Suddenly, on June 3, the acidity increased to 36 units and remained high for four days, until she again became indisposed, this time with an ordinary cold. Two days later, the free acidity was 14 units. It then climbed steadily until June 20, when it was 46 units, and the experiment was terminated. During the next twelve days, while *Mrs. P.* ate what she pleased, the trend of the gastric acidity was downward.

The impression gained is that, in this case, a deficient diet plus a sore throat or a cold greatly lowered the acidity. It seems probable that the sudden drop in acidity which took place a week before the throat became sore was due to the entrance of the infectious agent into the body. The sore throat was one of the most severe *Mrs. P.* had ever had. Curiously it did not produce enough immunity to protect her against the coming of the coryza; and curiously also, the coryza was not associated with any prodromal drop in acidity. Furthermore, so far as the acidity is concerned, recovery took place differently with the two infections. Since *Mrs. P. had not had a cold in nine* years, she may well be right when she suggests that the deficient diet probably lowered her resistance to respiratory infections. It is interesting to note that the concentration of pepsin was not affected either by the diet or the infections.

The question next arises: Do colds usually reduce gastric acidity in persons living on a normal diet? So far as we have gone, the evidence is against this assumption. In one young woman with functional indigestion and 20 units of free hydrochloric acid in the stomach, an analysis made when she had a cold showed 34 units. Similarly, in a young man with what appeared to be chronic mesenteric lymphadenitis, a gastric analysis made when he was feeling well showed 20 units of free hydrochloric acid; later, when he had a bad cold, there were 42 units, and still later, when he had an acute flare-up of his abdominal infection with a leukocytosis of 18,600 cells, there were 32 units of free acid in the stomach. Another young man with chronic headache and 40 units of free acid had 16 units four days later when he came down with a cold. A middle-aged woman, examined when she had a severe cold, had 20 units of free acid, which is not necessarily abnormal. Unfortunately, in this case, we could not get a control reading when she was well. The work of Vanzant (1931, 1932) (17, 18) and others showed that fever will reduce gastric acidity both in animals and man. Our impression is that the marked and sudden drops in acidity seen with respiratory infections in the case of *Mrs. P.* were due partly to the defective diet.

Mrs. P. gained 1 pound (0.5 kg.) during the first ten days on the deficient diet; later she lost 4 pounds (1.8 kg.), but she gained 2 pounds (0.9 kg.) before she began eating as she pleased. Except for the colds, she felt well throughout the experiment and had a good appetite. This is interesting because it is often said that the first result of eating food deficient in B_1 is loss of appetite.

As a subject for this experiment *Miss S.* had the advantage that her gastric acidity was often abnormally high, and she suffered at times with an ulcer-like syndrome. We hoped, therefore, to see what the diet could do for a person with an "ulcer constitution." Disadvantageous was the fact that she was nervous, temperamental and impressionable. This was reflected even in the figures for the basal metabolic rate. While there was almost no variation in the results of the two series of four tests each, made on *Dr. and Mrs. P.*, the results in the case of *Miss S.* were -27, -21, and -16%. Judging from Figure 3, the emotional instability was reflected much more in the curve representing concentration of pepsin than in that representing acidity.

It is hard to tell anything about the result of the experiment with *Miss S.* because she was so distressed and upset from the moment she went on the deficient diet that in two weeks she had to give up and go back to her usual ways of eating. It is conceivable that the low reading for free acid of 18 points, observed three days after she went back on a full diet, was due to the temporary lack of vitamin B_1, but this is improbable since the acidity fell to the same low level a month later when she was on a normal diet.

It may be worth noting that each of the three dips in the curve of free acidity appeared from nine to eleven days before the beginning of menstruation. In the case of *Mrs. P.* and the two women previously studied by Vanzant and Alvarez (1931) (19), the men-

to produce anemia. Some experiments by Strauss and Castle (1932) (22) suggested that part of the vitamin B complex may have something to do with pernicious anemia. Remissions were obtained in this disease by giving several types of extracts containing vitamin B.

In the cases of *Dr. and Mrs. P.*, the loss of hemoglobin was more marked than the loss of erythrocytes. Thus *Dr. P.* lost 11 per cent of his hemoglobin and 7 per cent of his erythrocytes; *Mrs. P.* lost 11 per cent of her hemoglobin and 8 per cent of her erythrocytes, and *Miss S.* in about thirteen weeks lost 11 per cent of her hemoglobin and gained 7 per cent in the number of erythrocytes.

Careful calculations of the iron content of the diet given the three volunteers shows that it approximated Sherman's standards for minimal requirements. It contained 0.0093 gm. as compared with the 0.010 gm. of the standard. From this it does not look as if the rapid fall in hemoglobin could have been due to a lack of iron. In view of the experience with beriberi, it is hard to blame it on the lack of vitamin B_1, and it is hard to say why the body continued to lose hemoglobin after it was supplied with a normal diet. No yeast or other rich source of vitamin B_1 was given during the period of recovery. It may be that the loss of hemoglobin came because the deprivation of vitamin B_1 was more severe than that observed even in an Oriental prison camp.

SUMMARY

Two persons were maintained for six weeks and one was maintained for two weeks on a diet markedly deficient in vitamin B_1. The vitamin/calorie ratio was 1.2 instead of the minimum of about 1.8, required on the basis of Cowgill's standard.

The concentrations of hydrochloric acid and pepsin in the gastric juice were measured almost every day. In two of the subjects of the experiment there were no definite changes in the gastric juice, and in the third the only changes consisted in two falls in acidity, each associated with a respiratory infection.

The two persons who continued with the experiment for six weeks felt well and enjoyed a good appetite; in fact, one was uncomfortably hungry the whole time. The third person was so apprehensive and upset from the start that in her case no conclusion can be drawn as to the effect of the diet.

The most striking change observed in all three persons was in the hemoglobin content of the blood. In all three persons, this fell off 11 per cent, while at the same time there was a drop of 7 or 8 per cent in the erythrocyte count. In the case of the man these losses were rapidly regained after the return to a normal diet. In the women recovery was slower. The loss of hemoglobin can hardly be ascribed to a deficiency in the iron content of the diet because the deviation from the minimal standard was so slight.

In the case of one of the women studied, menstruation did not seem to have any effect on the concentrations of acid or pepsin in the gastric juice. In the case of the other woman, it may be significant that the three lowest points on the curve representing acidity each preceded by about eleven days the beginning of menstruation.

The work here reported indicates that a diet deficient in vitamin B_1, by itself, is not likely to produce much reduction in gastric acidity. It is possible, however, that such a diet might reinforce the lowering effect on gastric acidity of fever induced by injections of foreign protein.

Two persons were maintained for six weeks and one was maintained for two weeks on a diet markedly deficient in vitamin B_1. The vitamin/calorie ratio was 1.2 instead of the minimum of about 1.8, required on the basis of Cowgill's standard.

The [illegible] in the gastric juice were [illegible]. In two of the [illegible] no definite change in the gastric juice [illegible] third the only [illegible] such as [illegible] with a [illegible].

The two persons who [illegible] for six weeks felt well and [illegible] in fact, one was uncomfortably [illegible]. The third person was [illegible] the start that in her case [illegible] as to the effect of the diet.

The most striking change observed [illegible] one was in the hemoglobin content of the blood. In all three persons this fell 11 per cent. At the same time there was a drop of 7 per cent in the erythrocyte count. In the case of the [illegible] losses were rapidly repaired after the return to a normal diet. In the women receiving [illegible] loss of hemoglobin could hardly be ascribed to a deficiency in the iron content of the diet because the deficiency in vitamin B_1 was so great.

In the case of one of the women studied [illegible] did not seem to have any effect on the secretions of acid or pepsin in the gastric juice. In the case of the other woman, it [illegible] the three lowest points on the curve [illegible] acidity each preceded by about eleven days the beginning of menstruation.

The work here reported seems to show that a diet deficient in vitamin B_1 by itself, is not likely to produce much reduction in gastric acidity. It is possible, however, that such a diet might [illegible] effect on gastric acidity of [illegible] of foreign protein.

Roentgenographic Studies of the Mucous Membrane of the Colon

I. The Normal Pattern

By

FRANZ J. LUST, M.D.

and

HARRY G. JACOBI, M.D.

NEW YORK, NEW YORK

DETAIL studies of the inner surface of the colon are rather difficult to obtain. Even more difficult however, is the interpretation of these mucosal patterns. A more generalized knowledge of this subject would certainly open up a large field of valuable information and help materially in the diagnosis of colonic lesions. This subject has not received, in this country, the attention that it merits. Abroad, such men as Kalkbrenner (1), Knothe (2) and Berg (3), have all utilized this method a great deal.

In order to appreciate fully the detailed musocal

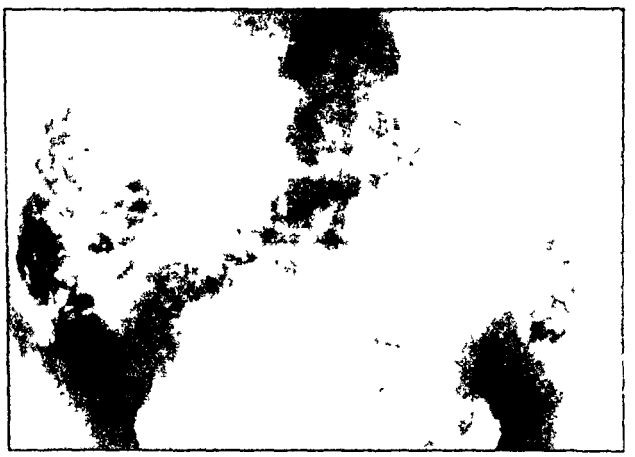

Fig. 1. General mucosal detail of colon obtained by use of our technique.

pattern which we are about to describe, it becomes necessary to sketch briefly the anatomical structure of this mucous membrane together with its physiological action.

The large bowel contains the mucosa, muscularis mucosae, submucosa, the muscularis propria, and the serosa. The mucosal folds which are observed in the colon, during different stages of activity, are not part of the permanent structure or pattern, but are the result of the so-called "plastic" action. The mucosal folds thus formed in this "plastic" action contain mucosa, muscularis mucosae and the submucosa. It is the roentgenographic reproduction of these folds by means of a thin layer of opaque material, which constitutes the main objective of this method. The very richly developed nerve fibres, in the form of Meissner's plexus and the ganglia of the muscularis mucosae, constitutes the local nerve apparatus which determines and controls this pattern formation. The muscularis propria by means of its circular and longitudinal fibres, plays an important part in regulating the calibre of the colon. By its action, alternating pressure and suction effects are created, producing a pumping effect. This acts as a regulatory mechanism for the movement of the colonic contents.

The bulk of the fluid contents of the colon also influences the mucosal pattern. The greater the amount of the contents, the more distended the viscus becomes and as a result, less of the mucosal detail is obtained. With the emptying of the colon, the reverse process takes place with the result that instead of visualizing only the edges of the gut, the actual details of the mucosal folds are obtained. Similarly when barium is introduced into the colon, moderately distending it, very little mucosal detail is possible. The success of the method here employed depends therefore upon the retention of only small amounts of the opaque mixture remaining in the colon, after the greater part of the opaque enema has been evacuated.

The normal mucous membrane relief of the various parts of the colon, reveals a more or less characteristic pattern formation and it is only by clearly understanding these normal appearances, that structural defects in the lining of the large gut, can be detected. In reality, however, the changes which are observed and reproduced are records of changes in the elasticity of the colon. This inherent elasticity is very sensitive to pathological processes which either by pressure or traction on the viscus, alter the normal musocal pattern.

PROCEDURE

The chief objective is to obtain an ideal distribution of the contrast substance throughout the colon, in as evenly a layer as possible. This layer must be so thin

HARRY G. JACOBI, M.D.

NEW YORK, NEW YORK

DETAIL studies of the inner surface of the colon are rather difficult to obtain. Even more difficult however, is the interpretation of these mucosal patterns. A more generalized knowledge of this subject would certainly open up a large field of valuable information and help materially in the diagnosis of colonic lesions. This subject has not received, in this country, the attention that it merits. Abroad, such men as Kalkbrenner (1), Knothe (2) and Berg (3), have all utilized this method a great deal.

In order to appreciate fully the detailed musocal pattern which we are about to describe, it becomes necessary to sketch briefly the anatomical structure of this mucous membrane together with its physiological action.

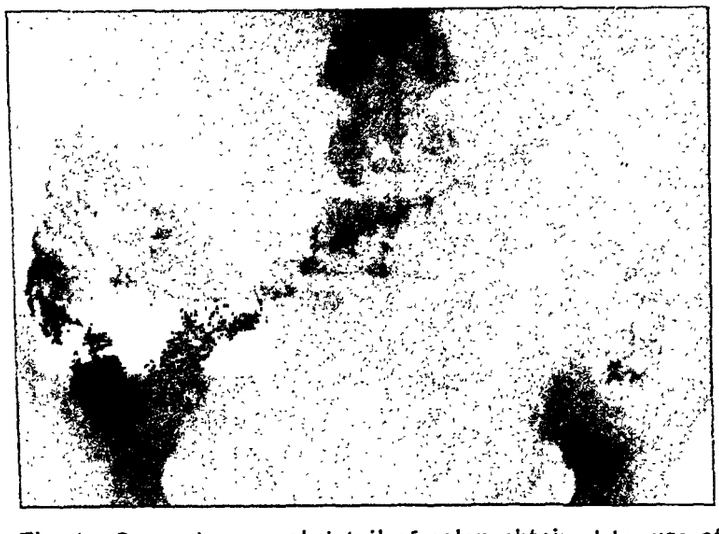

Fig. 1. General mucosal detail of colon obtained by use of our technique.

The large bowel contains the mucosa, muscularis mucosae, submucosa, the muscularis propria, and the serosa. The mucosal folds which are observed in the colon, during different stages of activity, are not part of the permanent structure or pattern, but are the result of the so-called "plastic" action. The mucosal folds thus formed in this "plastic" action contain mucosa, muscularis mucosae and the submucosa. It is the roentgenographic reproduction of these folds by means of a thin layer of opaque material, which constitutes the main objective of this method. The very richly developed nerve fibres, in the form of Meissner's plexus and the ganglia of the muscularis mucosae, constitutes the local nerve apparatus which determines and controls this pattern formation. The muscularis propria by means of its circular and longitudinal fibres, plays an important part in regulating the calibre of the colon. By its action, alternating pressure and suction effects are created, producing a pumping effect. This acts as a regulatory mechanism for the movement of the colonic contents.

The bulk of the fluid contents of the colon also influences the mucosal pattern. The greater the amount of the contents, the more distended the viscus becomes and as a result, less of the mucosal detail is obtained. With the emptying of the colon, the reverse process takes place with the result that instead of visualizing only the edges of the gut, the actual details of the mucosal folds are obtained. Similarly when barium is introduced into the colon, moderately distending it, very little mucosal detail is possible. The success of the method here employed depends therefore upon the retention of only small amounts of the opaque mixture remaining in the colon, after the greater part of the opaque enema has been evacuated.

The normal mucous membrane relief of the various parts of the colon, reveals a more or less characteristic pattern formation and it is only by clearly understanding these normal appearances, that structural defects in the lining of the large gut, can be detected. In reality, however, the changes which are observed and reproduced are records of changes in the elasticity of the colon. This inherent elasticity is very sensitive to pathological processes which either by pressure or traction on the viscus, alter the normal musocal pattern.

PROCEDURE

The chief objective is to obtain an ideal distribution of the contrast substance throughout the colon, in as evenly a layer as possible. This layer must be so thin

Submitted January 17, 1936.

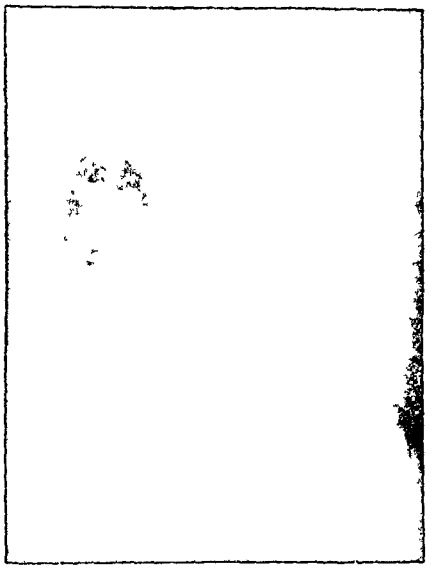

Fig. 4. Descending Colon showing the "parallel lines" arrangement of the mucosal folds.

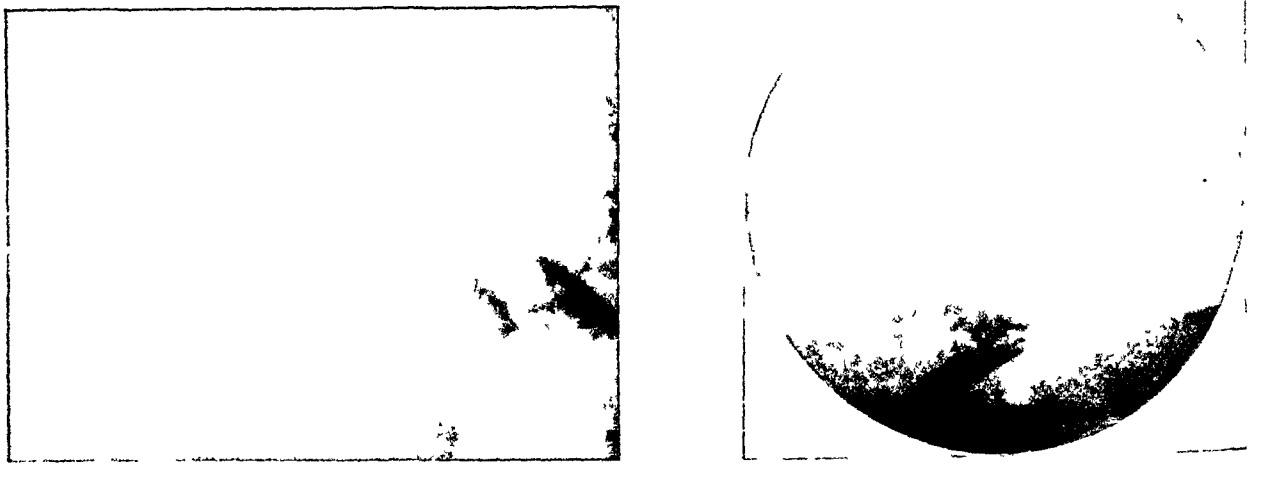
REPORT OF STUDIES

Roengenographically, the structure of the mucosal pattern of the colon appears as different forms and arrangements of alternating longitudinal and transverse folds. The transverse folds undergo a constant decrease in size as the terminal end of the colon is approached. As a result of this a different picture is imparted to the various portions of the colon.

Fig. 1: Shows the general effect which is usually obtained by following the above mentioned technique. On careful examination the general mucosal pattern of the different parts of the colon may be noted.



In the cecum, we find that the transverse folds are quite prominent and heavy and appear in a great variety of forms and combinations. As a result of this the transverse rugae can be seen running in different directions and at various angles to the axis of the cecum. This appearance constitutes the so-called usual mucosal pattern seen in the cecum. Fig. 2 shows this arrangement of transverse rugae in greater detail and when this picture is obtained, it is to be considered as fairly characteristic of the normal mucosal pattern of the cecum.

Fig. 3: Shows the mucosal pattern seen in the transverse colon. The main features observed in this portion of the colon may be summed up briefly as follows: (1) There is a marked uniformity of appearance noted throughout this entire region. (2) A decrease in the size of the transverse rugae occurs as compared with those of the cecum. (3) An increase takes place in the size of the longitudinal rugae. There is produced as a result of the above changes an arrangement of the rugae into alternating groups of transverse and longitudinal folds. The so-called haustral units are here seen as consisting usually of three transverse and the same number of longitudinal rugae. This formation can be seen particularly well in Fig. 3A. In most cases anywhere from two to four transverse folds usually alternate with an equal number of longitudinal folds. Sometimes, however, the axes of the transverse rugae appear somewhat distorted, resulting in a Y shaped or chain effect of the mucosal pattern, similar to that seen in Fig. 3B.

In the descending colon, the pattern again shows a change in the structural picture due principally to the diminished size of the transverse rugae. Usually, the transverse folds are so faint that the longitudinal rugae alone are visible. As a result of this there is imparted to the picture the appearance of a series of "parallel lines" which resemble very much that of railroad tracks. Fig. 4 demonstrates this arrangement very well.

In the region of the sigmoid the rugae are found to be much broader, and are mostly Y shaped in their arrangement. Fig. 5 shows the mucosal pattern seen in upper and lower sigmoid.

Sometimes a picture is seen similar to that in Fig. 6, where the mucosal pattern while having the usual form, becomes more or less disrupted or broken up in its outline. The normal general appearance however, is still retained. Some authors (Knothe) have interpreted such an appearance as being due to some form of irritation of the colon. Up to the present time

5 A 5 B

Fig. 5. A—Mucosal pattern of upper sigmoid. B—Mucosal pattern of lower sigmoid.

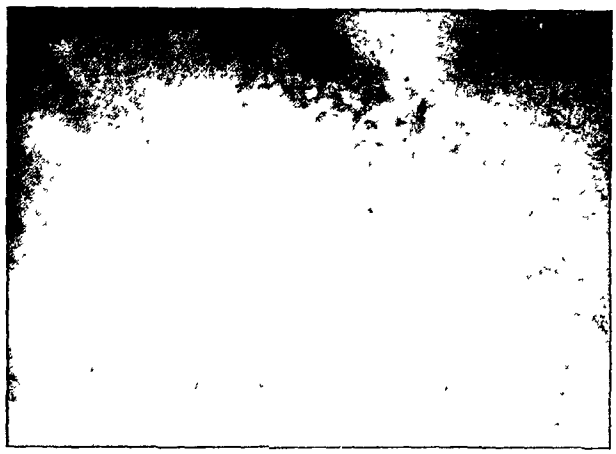


Fig. 6. Disrupted or "broken line" effect of mucosal pattern.

however, we have not become sufficiently convinced of this, and feel that this irregularity or interruption in the outline is nothing more than a variation of the normal picture and of no particular significance. It has therefore been so included in this report.

It must be emphasized that the careful study of the individual folds is just as important as that of the whole pattern. Normally the individual folds are clear cut, nearly straight with no irregularity in the outline. Any interruption in the regularity of the outline, is the result of pathological lesions.

DISCUSSION

The present work is based upon the studies of such pioneers in colon visualization as Forssell (4), Bergand Kalkbrenner (1), and Knothe (2). The investigations of the latter contain by far the more extensive and detailed study of the subject. In his work, Knothe also made use of the simple barium suspension, a method quite similar to ours'. Kalkbrenner recommended a thorium preparation as a contrast substance. Many other studies along these lines have been reported by several European investigators, (5), (6), (7). Our literature however, is quite lacking in the discussion of this excellent and helpful method.

There are several distinct advantages which this method has over that of the ordinary routine procedure which is at present in use in this country. (1) There is a marked reduction obtained in the so-called exaggerated redundancy of the colon with its consequent overlapping of intestinal loops. (2) The actual mucosal surface of the colon is visualized instead of the edges or borders of the gut. (3) The displacement and distortion of the flexures which invariably results from complete filling of the colon with barium or air is eliminated. (4) This method enables us to study more accurately the degree of contraction and elasticity of the colon wall. (5) Careful analysis of the altered appearances of the mucous membrane pattern is more clearly demonstrated due to changes in the normal elasticity of the colon wall. Such changes in the elasticity of the colon wall are chiefly due to pathological processes and can be most admirably demonstrated by this method.

Aluminum Hydroxide as an Antacid in Peptic Ulcer*

By

W. LLOYD ADAMS, Ph.D.†
I. H. EINSEL, M.D.
and
VICTOR C. MYERS, Ph.D., D. Sc.
CLEVELAND, OHIO

THE USE OF aluminum hydroxide in the treatment of peptic ulcer was introduced in Europe over ten years ago. In 1922 Roch (1) reported that "Colloidal hydrate of aluminum absorbs hydrochloric acid. It has proven in our hands the antacid medicament par excellence, quite superior to bicarbonate of soda, magnesia, subnitrate of bismuth, etc." Practically all reports up to the present time deal with the results obtained with proprietary preparations of colloidal aluminum hydroxide. Guillermin (2) called attention to the advantages of this drug over the other antacids, and Kagan (3) in listing its advantages states that "It absorbs excess of hydrochloric acid from the stomach, the acid-containing mass passing through into the intestines and finally being evacuated from the lower bowel. Colloidal hydrate of aluminum, therefore, actually removes from the system the causative acid radical (Cl) instead of temporarily neutralizing it." In 1929 Crohn (4) reported that a colloidal aluminum hydroxide reduced the emptying time of the stomach, lowered the gastric acidity and was devoid of deleterious side effects. Two years later Kreis (5) reported that the drug acted satisfactorily as an antacid, relieved pain, was efficient in small doses, and provided a protective coating to the ulcer surface.

This report presents data which have been obtained at the Cleveland City Hospital on patients suffering from chronic peptic ulcer who have received aluminum hydroxide medicament. Several clinical reports have been given since the introduction of this therapy at the Hospital in 1929 by one of the authors (E), one of them quite recently (6).

A group of twenty-five peptic ulcer patients comprised the first study (7). At that time powdered aluminum hydroxide (Merck and Mallinckrodt) was administered, one-half hour after meals, in doses of 4 grams in water. Observations were made on the acid-base balance of the plasma and on the aluminum content of the blood and the urine. Eleven complete acid-base balance studies were made on four patients, but no changes were noted which could be attributed to the therapy. Table I gives the findings on the aluminum content of the blood and urine in this series of six cases. The data appear to suggest a slight in-

crease in the excretion of aluminum in the urine after its ingestion. However, it must be borne in mind that the amount of aluminum in any case is very small (fraction of a milligram) and it is doubtful if any interpretation can be placed upon the figures other than that the amount of aluminum normally present in human blood and urine is very small and that this is not significantly altered even after large oral doses of Al(OH)$_3$. The method employed for these aluminum estimations was the colorimetric aurin method de-

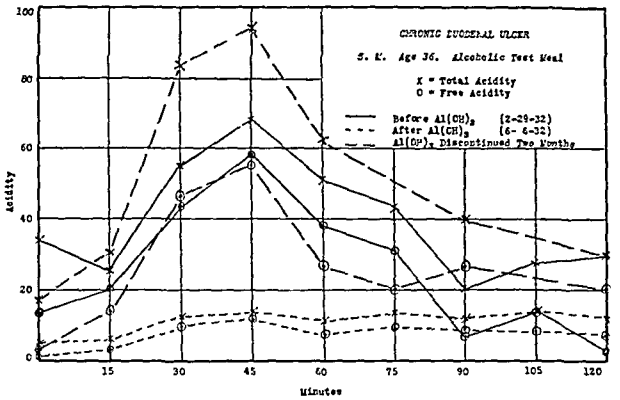

Fig. 1. Gastric acidity before and after receiving treatment of 1 dram $Al(OH)_3$ six times daily and one-half hour after meals (Colloidal $Al(OH)_3$).

scribed by Myers and Mull (8). It is probable that these figures are slightly too high, since Dr. Eveleth obtained an average of 0.076 mg. Al per 100 gm. for ten later blood analyses and 0.104 mg. Al in one 24 hr. urine specimen when traces of iron were removed by extraction in the form of ferric thiocyanate (6).

Inasmuch as relief was so rapid after beginning the treatment of chronic ulcer, it was assumed that the aluminum hydroxide powder neutralized the gastric acidity. Much to our surprise the powder was found to have practically no neutralizing power to HCl in vitro. This fact, and because of its easier administration, led to the preparation of a colloidal cream of aluminum hydroxide. Results with this preparation have been even more satisfactory than those obtained when the powder was used. The improvement may lie in the high neutralizing power of the cream: one c.c. of the cream neutralizes 20 c.c. of 0.1 N/HCl in a period of 4 hours. The neutralization is characterized by an initial rapid partial neutralization followed by a slow reaction until the end-point is reached.

Einsel and Rowland (9) reported unusual success in treating 13 ulcer patients with this colloidal aluminum hydroxide given in doses of 4 cc. six times per day one-half hour after meals. Even refractory cases, which had been treated with soluble alkalies for many months without improvement, responded immediately to this drug.

The study of the effect of aluminum hydroxide cream on the gastric acidity was begun with fractional analysis of the gastric juice after alcohol stimulation. Fifty cc. of 7 per cent alcohol were introduced into the fasting stomach and samples of the contents withdrawn at 15 minute intervals. Figs. 1-3 disclose that prolonged ingestion of aluminum hydroxide cream led to a marked diminution of the gastric acidity. Fig. 1 also shows that reduction of the dosage of the cream is followed by a rise in the acidity. Fig. 4 represents the acid picture in gastric analysis using Bloomfield's technique with histamine as a stimulant. Here, too, the acidity is found to be lowered after a period of aluminum hydroxide cream ingestion.

Up to this time it had been ascertained that the cream was peculiarly efficient in the relief of ulcer symptoms, that prolonged ingestion of the cream did not appreciably affect the aluminum content of the blood or its excretion by way of the urine, that no acid-base balance disturbance was apparent, and that continued ingestion of the cream was followed by a marked lowering of the acid curve of gastric acidity. The indications of Figs. 1-4 were responsible for the intense study of seven typical cases with special reference to gastric acidity and to acid-base balance of the blood. Data for five of these cases are given in Tables II and III below.

EXPERIMENTAL PROCEDURES

No food or liquid was given to the subject between the evening meal and the time of the gastric analysis the following morning. At approximately 8:30 A. M. the following procedures were carried out on all cases.

Unoxalated sample of blood from the median basilic vein was collected under oil without stasis, according to the technique of Myers and Muntwyler (10). A Rehfuss tube was then passed to the most dependent portion of the stomach and the entire contents of the fasting stomach withdrawn. The subject was urged not to swallow saliva and a pan was provided for expectoration. The entire gastric secretion was thereafter collected, by continuous aspiration, in 15 minute periods.

One-half hour after the withdrawal of the fasting contents (end of the second 15 minute period) 0.1 mg. of histamine per 10 kilograms of body weight was injected intramuscularly into the deltoid muscle. One hour after withdrawal of the first sample of blood (end of the fourth 15 minute period) another sample was drawn as before. Two or three 15 minute samples were aspirated after the last blood specimen was taken. Record was made of the volume and of the appearance of blood, bile and abnormal amounts of mucus in all gastric samples.

Each blood specimen was placed in a refrigerator immediately after collection until it could be transported to the laboratory. It was centrifuged at the end of the procedure on the Ward.

When necessary, the gastric samples were filtered through glass wool. Ten cc. of gastric juice were titrated with exactly 0.1 normal NaOH to the salmon pink color of dimethylaminoazobenzene. Duplicate chloride determinations on each gastric sample were made on 1 cc. of sample, using the Wilson and Ball (11) technique. The total base of each gastric sample was determined in duplicate by use of the method of Stadie and Ross (12), although after its publication, the simpler technique of Wright and Allison (13) was followed. The removal of phosphates was found to be unnecessary because of their low concentration in gastric juice collected under these conditions. In normal individuals the phosphorus content of the gastric juice was found by Helmer, Fouts and Zerfas (14) to be below 0.15 mg. per c.c. This is below the limit of interference according to Stadie and Ross. The totals for the 1½ hour period of the gastric analyses, half hour before and one hour after histamine, are recorded in Table II for the volume

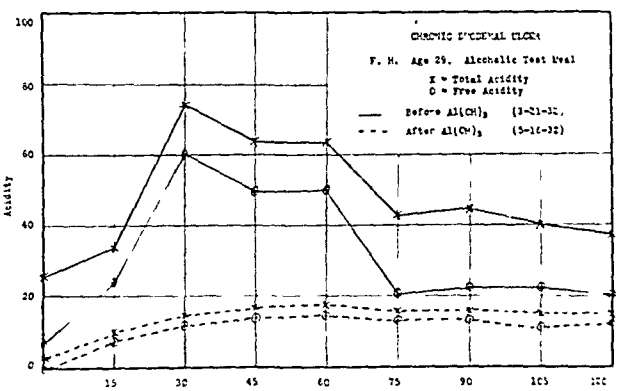

Fig. 2. Gastric acidity before and after receiving treatment of 1 dram Colloidal $Al(OH)_3$ six times per day after meals.

of gastric secretion and the free acidity, total acidity, total chloride and total base. The volume of the residuum is not included in the total volume.

After the blood samples had clotted and had been centrifuged, the serum was removed under oil and placed in a separate container. The carbon dioxide content of each sample was determined by the Van Slyke method (15), usually in duplicate. Chloride and total base determinations of the serum were carried out as mentioned above in the case of gastric analysis. Blood samples were taken for each set of gastric analyses, as the dates in Table III will show, the first being a control and the second, at the

*Analyses made before the beginning of $Al(OH)_3$ therapy.

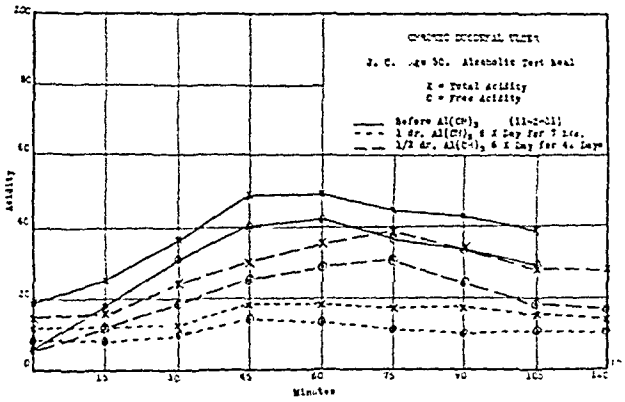

Fig. 3. Gastric acidity before and after receiving treatment as given above.

end of 60 minutes, being 30 minutes after the administration of histamine. Individual treatment is recorded in the protocols for each patient.

CASE PROTOCOLS

Case I. Hospital No. 109863. H. V., male, aged 35, truck driver, weight 140 lbs. Present illness was "pain in the abdomen." History revealed an operation for ulcer several years previous and on the strength of clinical and X-ray findings a diagnosis of duodenal ulcer was made. Patient was admitted to the hospital on Nov. 25th and placed upon a 4th day Sippy diet. Gastric analyses were made on Nov. 28th and 30th, before any aluminum hydroxide cream was given. On Dec. 1st medication consisting of 15 c.c. of $Al(OH)_3$ cream in 1 ounce of milk six times per day was begun. No other medication was given except an occasional prescription of 1 ounce of petrolagar twice a day. Gastric analysis was made on Dec. 5th and 7th after which patient was permitted to be up and around the Ward. Analysis was again made on Dec. 12. Patient was discharged on Dec. 14 and given aluminum hydroxide cream with instructions to take 4 cc. six times per day. The symptoms of which the patient complained upon entry were relieved as soon as the $Al(OH)_3$ therapy was instituted and at the time of discharge his condition and prognosis were very good. Gastric analysis was again performed on Jan. 18 when the patient visited the Out-Patient Clinic.

Case II. Hospital No. 109867. J. S., male, aged 55, white, laborer, weight 145 lbs. Present illness was complaint of epigastric pain. A diagnosis of duodenal ulcer was made on the strength of clinical and X-ray findings. There were no indications of retention but severe constipation was habitual. Patient was admitted to the hospital on Nov. 26th with severe pain in the epigastric region. Aluminum hydroxide cream, 8 c.c. six times per day, and the 4th day Sippy diet were immediately given. No other medication was given except an occasional sedative (luminal) on the evening of the day the gastric analysis was performed, and frequent enemas and suppositories. Relief of gastric symptoms was obtained immediately after the use of the cream. Gastric analyses were performed on Nov. 30th and Dec. 7th, 12th, and 16th. Patient was discharged Dec. 28th, clinically improved, and was given $Al(OH)_3$ cream with instructions to use it in dosages of 4 c.c. six times per day.

Case III. Hospital No. 112346. T. Mc., male, aged 54, white, salesman, weight 179 lbs. Present illness was attacks of substernal pain. Fluoroscopic examination and roentgenograms of the stomach showed an inconstant deformity of the duodenal bulb, which was persistent in the prone position, but no niche could be seen. No retention was found at 6 hrs. The changes were diagnosed as due to a duodenal ulcer and therapy for such was indicated by other clinical findings. Patient was admitted to the hospital on Jan. 27th and placed upon a first day Sippy diet until Jan. 30th when the convalescing Sippy diet was ordered. Gastric analysis was performed on Jan. 31st, and on Feb. 1st the first medication of aluminum hydroxide cream was given in doses of 8 c.c. six times per day. Gastric analysis was again made on March 11th. During the interval between hospitalization and this analysis, the patient had had no gastric symptoms and felt much improved.

Case IV. Hospital No. 112601. A. E., male, aged 46, white, unemployed, weight 155 lbs. Present illness was "pain in the stomach." Fluoroscopic study and roentgenograms revealed a large benign ulcer of the lesser curvature of the stomach measuring about 3½ c.c. in diameter. Thirty per cent retention at 6 hours was found and a niche indicating a duodenal ulcer was also present. Second examination, 25 days later, showed the niche to be smaller. Patient was admitted to the hospital on Feb. 1st and placed upon a liquid diet. On Feb. 4th the convalescent Sippy diet was ordered. Gastric analyses using 50 c.c. of 7 per cent alcohol as a stimulant were performed on Feb. 7th and 10th. Four c.c. of $Al(OH)_3$ cream six times per day was ordered beginning on Feb. 9th and histamine analyses were made on Feb. 17th and 22nd and on March 1st and 4th. Through error the patient was permitted to take 8 ounces of magnesium citrate water on Feb. 15th. The improvement in the patient was such that he was released to the Out-Patient department on March 7th with instruction to continue on 4 c.c. of the cream daily and to report weekly.

Case V. Hospital No. 53955. G. V., male, aged 47, white, plasterer, weight 128 lbs. Present illness was described as "stomach trouble" with epigastric burning 2 to 3 hours after meals. Fluoroscopic examinations and pictures of the stomach showed thickening of the rugae of the stomach and peristaltic waves having a spastic character at times. On both examinations the stomach was very active and showed an area of constriction about 1 cm. beyond the pyloric canal. This constriction varied in width indicating that, besides an organic deformity, a spastic condition was also present. A niche measuring about 8 mm. in diameter could be seen about the mid-portion of the bulb a little nearer to the greater curvature side. At 6 hours no retention was found. The diagnosis was duodenal ulcer with possibly another at the pyloric canal. This patient was followed in the Out-Patient department and reported severe pains which awakened him at 3:00 to 4:00 A. M. Food was found to relieve the pain somewhat. No vomiting or nausea was present but the bowels were very constipated. No blood was passed in the stools. Mild tenderness could be elicited in the epigastric region. Gastric analysis was made on March 18th and the patient was placed upon 4 c.c. of $Al(OH)_3$ cream six times per day immediately thereafter. Subsequent analyses were made on March 25th and April 15th and 21st. After beginning the cream no distress was reported at any time except that a headache usually occurred after an analysis. Patient last reported to the Clinic on May 19th. No distress occurred since therapy was instituted.

DISCUSSION

During the past several years one of us (E.) has treated over 125 peptic ulcer patients with colloidal aluminum hydroxide and obtained uniform clinical results. Within a few days after beginning the cream all burning, nausea, and pain disappear. Feedings are taken without distress and weight gradually increases. There have been no idiosyncrasies to the drug, no vomiting, no toxic symptoms or complaints or evidence of gastric intolerance.

The typical cases which have been studied intensively do not disclose the ultimate mechanism of the beneficial results in the use of aluminum hydroxide

cream. However, some very important and interesting results of its use are apparent.

Gastric Analyses. The volume of gastric secretion for a 90 minute period shows a tendency to decrease after the administration of colloidal $Al(OH)_3$. In the course of a single analysis the volume shows, in many cases, a small decrease for the second 15 minute period.

TABLE III

Acid-Base Findings of Blood. First specimen taken before test meal, second specimen sixty minutes after meal

This has been attributed by Bloomfield and Keefer (16) to the subsidence of stimulation arising from the passage of the Rehfuss tube.

The concentration of free acid in the first and second 15 minute specimen shows a decrease, in most analyses, as the duration of $Al(OH)_3$ therapy increases (see Table II). This is a very significant finding inasmuch as reduction in gastric acidity is one of the primary objects in treating ulcer. The decrease begins to show immediately after the initiation of the treatment and shows a progression to a lower level. Thus less irritation to the ulcer is present, and the amount of alkali required for the neutralization of the stomach contents as they pour into the duodenum is decreased. The efficacy of the colloidal aluminum hydroxide must then rest, at least partially, in the reduction of the concentration of free acid. Its slight astringency and demulcent properties are doubtless also important therapeutic properties.

It is natural that since aluminum hydroxide cream is used as a colloidal protein precipitant, its effect on the stomach mucosa should be questioned. One of the most important findings with regard to the free acid concentration is the fact that histamine can elicit approximately the same concentration at the height of stimulation, before and after the use of aluminum hydroxide cream. This is an indication that the cream does not impair the ability of the stomach to secrete acid.

In cases showing high acid values the free acid curves and the total acid curves are closely parallel. It follows that the highest total acid concentration occurs in those specimens which show the highest free acid concentration. Especially is this true in analyses using histamine as a stimulant. The analyses reported here agree with the findings of many other workers to the effect that as the secretion volume increases under histamine stimulation, the free acid concentration rises and the character of the gastric secretion becomes less mucoid. The highest acid concentration was usually reached in the second 15 minute period after the injection of histamine, but occasionally it was not attained until the next 15 minute specimen. Varying rates of absorption of the histamine could very easily account for this. It may be noted that the greatest amount of free acid is not always secreted in those periods showing the highest acid concentration.

Berglund, Wahlquist and Sherwood (17) demonstrated that the total chloride was a true index of the acid secretion of the stomach stimulated by histamine. They believed that only insignificant amounts of chloride existed in the gastric juice in a form other than as HCl. The difference between free and total acidity was considered as due to combination of HCl with mucus. Considering the total acidity of these cases it is found that the individual specimens show a high degree of correlation; thus supporting the above workers.

Polland, Roberts and Bloomfield (18) studied the chloride, base and nitrogen content of the gastric juice after histamine stimulation. They found that the rise of chloride concentration was paralleled by an increase in volume but the latter was observed to fall more quickly than the former. In these cases, however, it is noted that the total chloride concentration and the volumes are parallel throughout the rise and fall of secretion.

Further evidence that no permanent injury is done to the secreting cells of the stomach is contained in those cases where values for total chloride secreted in 90 minutes rose again when the dosage of aluminum hydroxide cream had been reduced to one-fourth its former value.

The total base shows no close correlation with the volume of secretion in these cases (Table II), but the total base values are closely correlated by an inverse relationship to the figures for free and total acid concentration. Bulger, Stroud and Heideman (19) studied the electrolyte variation in human gastric juice obtained by water stimulation and found that relatively little change in the concentration of chloride attends secretion but that the total base falls in proportion to the increase in acid under their experimental conditions. Austin and Gamon (20) found that the period of maximal sodium secretion after histamine is previous to the period of maximal acid secretion and not when the acid secretion is subsiding. The potassium content remained approximately constant while the

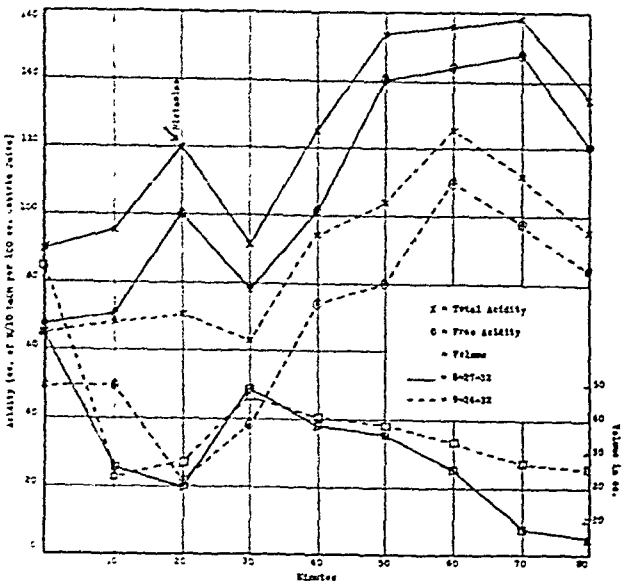

Fig. 4. Bloomfield gastric analysis on chronic duodenal ulcer case before and after treatment with a Colloidal $Al(OH)_3$.

amounts of calcium and magnesium were so small that their variation was not easily determined. Polland, Roberts and Bloomfield (18) found a general decrease in base concentration as the volume of secretion increased, and noted also that the base and volume fell together for a period, indicating that dilution was not alone the factor responsible for the decrease in base concentration. However, in the present study the correlation of total base and the volume of secretion is very poor, although the general tendency is for the least concentration of base to occur when the volume is greatest.

Blood Findings. The disturbance of the acid-base equilibrium of the body which accompanies the ingestion of large quantities of soluble alkali has been reviewed by Gatewood, Gaebler, Muntwyler and Myers (21). Wildman (22) made a valuable contribution to the subject of chloride metabolism and alkalosis in peptic ulcer cases receiving bicarbonate therapy. He found that there must be a marked reduction of chloride reserve in the body before gastric secretion is definitely affected, and that acid secretion cannot be controlled by restriction of chloride intake. When gastric secretion is lowered by hypochloremia the ratio of chloride in the corpuscles to the chlorides in the plasma $\frac{(Cl_c)}{(Cl_p)}$ is reduced. Similarly the ratio of chlorides in the tissue cells to the chlorides in the tissue fluids $\frac{(Cl_c)}{(Cl_f)}$ is reduced. He suggests that the lowering of this ratio in reference to the sensitive nerve cells may be the basis of the apparent dysfunction of the autonomic system as seen in the symptoms of alkalosis.

The search for a suitable insoluble antacid finally led to the trial of aluminum hydroxide preparations because they are not absorbed and have antacid properties. Myers and Killian (23) determined that approximately 25 per cent of the aluminum from ingested baking powder residues supposedly in the form of $Al(OH)_3$ was in solution in the stomach and duodenum when straight sodium aluminum sulfate baking powders were used. However, the investigations of Myers and Mull (24), Myers and Morrison (25), Wührer (26) and others prove that there is practically no absorption of aluminum from the intestinal tract. No apparent disturbance in the mineral metabolism of the body by the ingestion of even large quantities of aluminum is found.

It was found by Dodds and Smith (27) that during the first 40 minutes after a meal the whole blood, plasma, and corpuscle chloride content showed a fall which they attributed to the beginning of gastric secretion. During the period between 45 and 90 minutes the whole blood showed a recovery to normal with an increase in corpuscle content above normal. The plasma chloride remained low. Gram (28) studying the serum chloride in various diseases found that an increase or decrease is accompanied by a corresponding percentage change in whole blood chloride. Arnoldi (29) had observed that the chloride of serum is altered during digestive activity and that in hyperacidity the amount was less than in hypoacidity. Molnar and Hetenyi (30) on the contrary, found that the serum chloride remained within the normal limits, although towards the lower bracket in anacidity and toward the upper in hyperacidity. Lim and Ni (31) reported that the fall in blood chlorides during histamine stimulation was greater in the corpuscles than in the plasma. A lowering of plasma chloride averaging 23 mg. was found by Jordan (32) in patients receiving soluble alkali therapy for ulcer. Bloch and Serby (33) found that the blood chloride picture did not differ from normal in 20 ulcer cases which they studied.

The data obtained in this study show, however, that no hypochloremia existed even after the aluminum cream had been ingested for several months. The normal range of plasma chlorides in terms of milli-equivalents is from 99 to 108 per liter. Assuming that the normal serum chloride level is about the same as that of the plasma, we find that most of the serum chloride figures observed in this investigation, both before and after the cream was given, fall in the lower limits of the normal range. However, no variation is found in a given individual during the height of stimulation of gastric secretion by histamine.

The total base findings, both before and after histamine stimulation, show no change in concentration within the limits of experimental error. The determinations were made in duplicate and all values obtained, both before and after the use of the aluminum cream, fall within the normal range for serum, but have a definite tendency toward the lower limit. The values range from 142 to 157 milli-equivalents per liter.

Berglund, Wahlquist and Sherwood (17) found that a close correlation existed between the highest total chloride concentration in a gastric analysis and the blood base concentration. Sunderman (34) did not find this in patients with pneumonia. In our data the correlation exists in most cases.

The alkaline reserve of the plasma (CO_2 capacity) is an adequate index of the acid-base balance only as long as variations from the normal are compensated. Therefore, the determination of the blood pH is highly desirable in the study of the acid-base balance. Since it was impractical to make such determinations under the conditions of this investigation, the chloride, total base, and carbon dioxide content had to be relied upon for information concerning the acid-base equilibrium.

However, acid-base determinations, including pH, were made on a single case receiving 108 c.c. of alumina cream daily for one week, the data being reported elsewhere (6). The variations in the pH (0.03) were within the limits of error of the method. Myers and Booher (35) studied the blood of patients with peptic ulcer receiving alkali treatment and found "that the bicarbonate invariably rises before the pH becomes abnormal." Jordan (37) studied the acid-base equilibrium in similar cases and found that toxic symptoms of alkalosis did not occur until the carbon dioxide content had risen above 70 volumes per cent. On this evidence it seemed that a study of carbon dioxide content would be profitable as an indication of acid-base balance variations in this study.

The highest figure for carbon dioxide content in any instance in these cases is 69 volumes per cent. This occurred in Case II before any aluminum cream had been administered. One week later it had fallen to 59 volumes per cent. In most instances the carbon dioxide content did not rise above 60 volumes per cent, and at no time did any subject show a value exceeding 70 volumes per cent. The highest content found while a patient was receiving aluminum hydroxide cream was not above 65 volumes per cent.

Histamine injection in the amount used in these cases does not cause any marked change in the carbon dioxide content (36, 37). The highest difference between the level before and after the injection was 6.8 as seen in Case I. Other factors such as increased ventilation, etc., may be instrumental in creating this difference, although care was exercised to minimize these factors. It is believed, however, that these additional factors are largely instrumental in producing the difference between the levels of CO_2 before and after the injection, rather than the injection itself, inasmuch as the difference is less than the experimental error in many cases.

The blood data in Table III show that no significant deviation from the initial level occurs in the chlorides, total bases, or carbon dioxide content of the serum after the use of colloidal aluminum hydroxide as an antacid, nor do they significantly change at the height of gastric secretion under histamine stimulation in these cases. A possible compensatory mechanism which would temporarily balance the secretion of large amounts of hydrochloric acid in the stomach is seen in the findings of Neale and Klumpp (38) who observed an increase in the alkalinity of the pancreatic secretion during histamine stimulation of the gastric secretion.

SUMMARY

The present observations on the effect of colloidal aluminum hydroxide upon the gastric secretion and upon the blood serum chlorides, total base and carbon dioxide content lead to the following conclusions:

1. With respect to the secretion of gastric juice after the ingestion of colloidal aluminum hydroxide:

The highest acid concentration of the gastric secretion after the intramuscular injection of histamine usually occurs between 15 and 30 minutes after the injection and occasionally during the following 15 minute period, showing that no change from normal occurs.

The greatest amount of acid is not always secreted in the 15 minute period yielding the highest acid concentration.

The total chloride concentration is an adequate index of the acid concentration, as is normally the case.

The total chloride concentration and the volume of secretion usually show a parallel rise and fall.

The total base concentration of the gastric juice is closely correlated to the free and total acid concentrations and hence to the total chloride concentration.

Only a general correlation exists between the volume of secretion and the total base concentration or the total amount of base per specimen.

2. With respect to the use of aluminum hydroxide as a gastric antacid:

A decrease in the total amount of acid secreted occurs in 90 minutes, this decrease being especially marked in cases of hyperacidity.

A decrease in free acidity of the gastric juice is shown by lower figures for free acid concentration in the two specimens collected at each analysis before the injection of histamine.

While the decreases mentioned are manifest immediately after administration of the colloidal aluminum hydroxide, a progression toward a lower level of acidity is seen with the duration of its use.

It would not appear that these decreases in acidity are the result of any permanent damage to the secreting mechanism, since histamine continues to elicit the same high acid concentration even after this antacid has been administered for several months, and further since a reduction in the dosage results in a rise towards the pre-treatment level.

Judging from a review of the literature on gastric antacids, from the observations on the relief of the symptoms of peptic ulcer in this study, and from the laboratory findings here reported, it appears that colloidal aluminum hydroxide is the most satisfactory antacid thus far employed.

3. With respect to the acid-base equilibrium of the blood of patients receiving aluminum hydroxide for a period of several months:

No significant change occurs in the serum chloride, total base or carbon dioxide content but the small changes exhibited show a tendency for the total chlorides to rise, and the carbon dioxide to fall—away from alkalosis.

No significant change occurs in the serum chloride, total base or carbon dioxide content one-half hour after the intramuscular injection of 0.1 mg. of histamine per 10 kilo of body weight.

The use of colloidal aluminum hydroxide over a period of several months is attended by no disturbance in the acid-base balance of the blood.

SECTION VI—*Abdominal Surgery*

Diverticula of the Jejunum: Report of Four Cases*

By

THOMAS J. JONES, M.D.

and

GEORGE CRILE, Jr., M.D.

CLEVELAND, OHIO

RANKIN *and Martin in reviewing* 111 *cases of* diverticula of the duodenum and three cases of diverticula of the jejunum in which the diagnosis was made by roentgen examination of the gastro-intestinal tract, concluded that (1) diverticula of the duodenum are of less clinical importance than diverticula elsewhere in the small bowel (2), no typical symptoms can be ascribed to diverticulosis of the small bowel, and (3) careful medical management seems to be the best procedure in the majority of the cases, although occasionally surgical intervention seems warranted.

Reviews of the literature on diverticulosis of the jejunum have been made by Gisbertz (2), and by Helvestun (3), and cases have recently been reported by Beigler, Bloom and Wruble (4), and by Schmidt and Guttman (5). All authors agree that no specific syndrome is associated with diverticulosis of the small bowel, that clinical diagnosis is usually impossible, and that careful medical management is the treatment of choice. Occasionally, however, the symptoms resulting from diverticula of the small bowel are so intractable that surgical intervention is necessary as is illustrated by the following case.

CASE REPORTS

Case 1: The patient was an unemployed painter, 32 years of age who entered this Clinic complaining of a gnawing epigastric pain which came on 45 minutes after meals. The pain was relieved by food, but was not relieved by soda. These attacks which had been present for 2 years preceding our examination were accompanied by

*From the Cleveland Clinic.
Submitted February 10, 1936.

some eructations and were aggravated by fatty foods, cabbage, and onions. At the onset of the gastro-intestinal disturbance, the patient had had an attack of agonizing colicky pain which began in the region of the umbilicus and radiated into the right lower quadrant. This pain was accompanied by nausea and vomiting and was so severe as to require morphine for relief. Two days before entry, the patient had had a similar attack of pain which had lasted for 12 hours. There was no history of jaundice, fever, or clay-colored stools.

For the past three years, the patient had had severel frontal headaches which lasted from 12 to 24 hours and were accompanied by nausea and vomiting. Ordinary dietary and medical management had given him no relief.

Physical examination revealed no abnormal findings. The heart and lungs were normal, the abdomen was flat and soft, and there were no masses palpable, no enlargement of the liver or spleen, and no tenderness was present.

Laboratory studies showed that the urine was entirely normal. The red blood cells numbered 4,790,000; white blood cells, 5,800; and the hemoglobin was 97 per cent. The blood sugar was 116 mg. per 100 c.c. five hours after eating and the Wassermann and Kahn tests were negative. An Ewald test meal was given and the free acid was found to be 38 and the total acid was 51 per cent. A cholecystogram was reported to show a normally functioning gall bladder without stones. The stomach and duodenum were reported to be normal except for a diverticulum 3 cm. in diameter which was attached to the first portion of the duodenum. This remained filled for 24 hours. The colon was normal.

Because of the severity of the patient's symptoms and the failure of medical management, excision of the diverticulum was advised.

Operation: (Dr. Jones). On October 16, 1935, an upper right rectus incision was made under spinal anesthesia and the gall bladder and liver were explored and found to be entirely normal. A normal appearing appendix was removed and its stump was inverted. The transverse colon was then pushed upward, an incision was made in the parietal peritoneum and the duodenum was exposed. The entire duodenum was carefully explored but no trace of a diverticulum or any other abnormality could be found. Finally, however, a pouch was seen over toward the midline; this pouch was grasped, dissected out and found to originate from the posterior wall of the jejunum at a point 2 cm. below the ligament of Treitz. The sac was dissected free down to a base about 2.5 cm. in diameter which was grasped with a Kelly clamp. The pouch was then excised and its base closed over by two lines of continuous inverting sutures. The abdomen was closed in layers in the usual manner.

Pathology report: Pathologic examination of the excised diverticulum showed that it was 4 cm. in length, 2.5 cm. in diameter at the orifice and 1.3 cm, in diameter at the distal end. The walls of the diverticulum varied from 1.0 to 2.0 mm. in thickness and were composed of normal jejunal mucosa covered by a thin fibrous coat. There was no active inflammation or ulceration.

The appendix showed a patent lumen, a moderate amount of lymphoid tissue, but no evidence of acute or subacute inflammation.

The postoperative course was uneventful, the maximum temperature being 100.4° F. and the pulse never rising above 100. The patient was discharged on the fifteenth postoperative day at which time he was able to take a full soft diet and he experienced no dyspepsia or abdominal pain.

A letter from the patient six weeks after the operation stated that he was eating a full diet, had had no recurrence of the gastro-intestinal symptoms, and that the headaches had been much less frequent and severe and that he felt entirely well.

Only three other cases of diverticulum of the jejunum have been seen at the Cleveland Clinic. In each case, the diagnosis was made from information gained from the roentgen examination.

Case 2: The patient was a woman 67 years of age. Roentgen examination of the stomach showed an ulcer in the pars media on the lesser curvature, two large diverticula from the second portion of the duodenum, and multiple diverticula from various parts of the small intestine. The only symptoms were indefinite abdominal distress which occurred chiefly in the left upper quadrant two hours after meals. It is, of course, impossible to state whether the symptoms in this case were due to the ulcer or to the diverticulosis. In view of the patient's age and the multiplicity of the lesions, medical treatment was advised.

Case 3: The patient was a man 42 years of age who was admitted complaining of a sour stomach, belching, and a sensation of epigastric fulness and soreness. All symptoms were of 10 years' duration but there had been frequent remissions of several months duration. The distress came on 10 or 15 minutes after meals and lasted four or five hours. Food or soda gave temporary relief. The patient had lost 30 pounds in weight. There had been no vomiting and no colicky pain or jaundice.

Physical examination: Physical examination revealed no abnormality except slight epigastric tenderness. Roentgen examination of the gastro-intestinal tract showed a non-obstructing duodenal ulcer, a normally functioning gall bladder without stones, and a normal colon. In addition, one film showed a probable diverticulum of the jejunum. There were 69 units of free hydrochloric acid and 88 units of total acidity after an Ewald meal. Blood counts, urinanalysis and all other routine laboratory studies gave findings within normal limits.

Diagnoses of duodenal ulcer and diverticulum of the jejunum were made, and the patient was given a modified Sippy diet with milk and cream and calcium carbonate powders between meals.

Six weeks later, a letter from the patient's wife stated that his stomach troubled him much less, although he still occasionally experienced a sensation of epigastric soreness.

Again in this case, it is probable that the symptoms were the result of the ulcer and not of the diverticulum.

Case 4: The patient was a married woman 40 years of age who came to this Clinic in December, 1925, complaining of severe frontal headaches, loss of appetite, vomiting after meals, and of a constant, severe, burning, epigastric pain which was aggravated by food. She had lost much weight and red blood had appeared in the stools on three or four occasions. All symptoms were dated to the time of a fall three months prior to entry.

Physical examination revealed no abnormal findings except for marked epigastric tenderness and tenderness at McBurney's point.

Laboratory findings: Routine studies of the blood and urine revealed no abnormalities. Roentgen examination of the gastro-intestinal tract showed a diverticulum of the second part of the duodenum, a second diverticulum at the duodenojejunal junction, and one farther along in the small intestine.

At operation, Dr. George Crile, Sr., found a large number of diverticula in the mesenteric border of the small bowel. The larger ones were dissected free, ligated and their stumps inverted by means of purse-string sutures. The postoperative course was uneventful except for a slight wound infection. On the eighteenth day after operation, the patient was discharged from the hospital.

Six months later, she stated that her general condition had improved strikingly, and that she was having no abdominal pain and only occasional headaches.

DISCUSSION

In cases 1 and 4, the patient's symptoms were, in all probability, the result of the diverticula but in the other two cases, it is unlikely that the diverticula represented more than an incidental finding. Certainly, the active peptic ulcers present in cases 2 and 3 were sufficient to explain all symptoms.

The association of severe headaches with the abdominal distress in the two cases in which the abdominal symptoms were definitely caused by the diverticula is interesting, although the series is of course too small to make these observations of any value. Diminution of intensity and frequency of the headaches occurred in both cases after the removal of the diverticula.

Unfortunately, there is nothing specific in the histories of patients with diverticula of the small bowel that can aid in making the clinical diagnosis. If however, a patient has gastro-intestinal symptoms consisting of pain and eructations following meals, if there is no roentgen evidence of peptic ulcer or of biliary disease, and if disorders of the colon can be excluded, it is well to bear in mind the possibility of a diverticulum of the small bowel and refer the patient to the roentgenologist with a request that especial attention be given to this question so that appropriate examinations can be made.

Medical management, emphasizing a bland diet and barium sulphate or olive oil given before meals, is often sufficient to control the symptoms referable to diverticula of the small bowel, but when the diverticula are in the jejunum, the symptoms are not infrequently quite intractable and surgical intervention becomes necessary.

SUMMARY

1. Four cases of diverticula of the jejunum are reported.

2. In one case, roentgen examination showed that the diverticulum appeared to arise from the first part of the duodenum, but at operation, it was found to come from the jejunum just below the duodenojejunal junction.

3. The two patients who did not respond to medical management were completely relieved of symptoms by excision of the diverticula.

4. There is no characteristic syndrome which makes possible a clinical diagnosis of diverticulum of the small bowel.

5. Persistent pain and eructation after meals in the absence of peptic ulcer, biliary disease, or disorders of the colon should suggest the possibility of a diverticulum of the small bowel, particularly if the symptoms are accompanied by severe headaches.

SECTION VII—*Surgery of the Lower Colon and Rectum*

Ischio-Rectal Abscess: A Stage in the Development of "Horseshoe" Fistula*

A Case Report

By

GEORGE M. LANDROCK, M.D.†
PHILADELPHIA, PENNSYLVANIA

THE patient, a male, twenty-eight years old, came to the dispensary on November 9th, 1935.

He gave a history of sudden onset of malaise, fever and inability to sleep for two nights on account of throbbing pain and swelling to the right of the anus.

Examination revealed a circumscribed swelling involving the right ischio-rectal fossa. The overlying skin was reddened, felt hot and indurated, and was tender upon pressure. There was, in the central portion, a small area the size of a quarter, which was paler in color and fluctuation was noted upon careful palpation. At examination the pain was so severe that neither digital nor instrumental examination was deemed necessary.

An *emergency diagnosis* of acute ischio-rectal abscess seemed logical.

Operation: Under local anesthesia, a paramedian incision was made into the abscess cavity. About four ounces of foul-smelling pus were evacuated, the fluid being under considerable tension. The patient was told to take hot sitz baths twice daily and to apply hot moist boric acid dressings locally, and was admitted to the hospital on the following day for further operative procedure.

The patient stated he had suffered from piles, (his own diagnosis) for many years and had sought relief by self medication with various ointments and suppositories.

†Graduate Student in Proctology, Graduate School of Medicine, University of Pennsylvania.
Submitted February 28, 1936.

Upon admission at the hospital his temperature was 99.6° F. and pulse rate 70. The blood pressure and urinary findings were within normal limits. Discharge from the incised abscess was scant and there was slight redness and induration of the overlying skin.

Under gas-ether anesthesia, the previous incision was enlarged. All septa were broken down for better drainage. The infection involved the anterior and posterior portions of the right ischio-rectal fossa. There was a communication posteriorly with the fossa on the opposite side, forming a posterior "horseshoe" abscess and fistula.

At operation, the internal opening was found in a posterior crypt. The fistulous tract extended downward, dividing into two branches, just proximal to the external sphincter, one communicating with the abscess through a short tract between the internal and external sphincters, and the other continuing superficially under the anal skin, ending at the posterior commissure. A hook was inserted into the crypt and this superficial tract *excised*, leaving the external sphincter intact. The deep tract was not divided at this time. A stab wound was made over the posterior portion of the left ischio-rectal fossa and a rubber tube inserted to afford through and through drainage. The cavity was packed lightly with gauze.

Post-operative treatment consisted of hot moist boric acid compresses changed frequently. The gauze dressing was removed on the day after operation. The rubber drain was removed on the third day. The wound was treated daily with a mild antiseptic until the patient's dismissal from the hospital on the eighth day. Thereafter he was seen twice a week, the cavity healing by granulation in about seven weeks, except for a small short sinus at the posterior angle of the wound. He was last seen on January 10th, 1936, at which time the sinus was still present. If this sinus does not heal, further division may be necessary.

Perianal Lipoma: A Case Report*

By

MAX I. LOMAS, M.D.†

PHILADELPHIA, PENNSYLVANIA

THE patient, a Negro, male, aged 51 years, registered at the Clinic October 19th, 1935, complaining of a "lump" near the anus on the left side. An operation for a "swelling" at the same site had been performed at another hospital eight years previously.

Six months before admission the patient noticed the present swelling. Local soreness was present occasionally. No discharge had been noticed.

Family history and past personal history were unimportant except as noted.

Examination revealed a swelling three inches long and two inches wide, one and one-half inches to the left of the anus. The swelling was moderately firm, showing no definite fluctuation. No local heat nor tenderness could be detected. Examination of the anus, rectum and sigmoid revealed no abnormalities. Inspection of the rest of the body showed no swellings or tumors of the same type.

A tentative diagnosis was made of a perianal lipoma or a 'cold" abscess. The swelling was incised under gas-ether anesthesia. The tumor was found to consist of fatty tissue. This was enucleated down to the ischio-rectal fossa where it apparently was continuous with the fat of this fossa. A ligature was placed around the base of the tumor and the tumor was excised. The wound was closed by interrupted sutures and healed by primary union.

Although fatty tumors of lipomata of the buttock frequently are reported, perianal lipomata continuous with or contiguous to the normal fat contained in the ischio-rectal fossa are not commonly encountered.

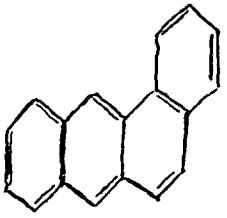
Annual Abstracts of Protologic Literature

(May, 1934-May, 1935) By CLEMENT L. MARTIN, M.D., Chicago, Illinois

The complete bibliography from which these Abstracts were made will be published in full in the Transactions of the American Proctologic Society, 1935.



ANESTHESIA

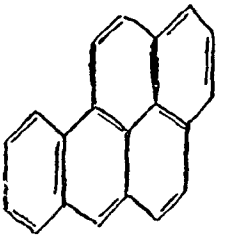
Spinal anesthesia is finding its place; it has gained wide usage as the details of its administration have become better known. A number of surgeons have completely abandoned it after liberal trial, some anaesthetists still use it fearfully but surgeon and anaesthetist have another valuable addition to their armamentarium in properly used spinal block analgesia. Trans-sacral and caudal block analgesia has the commendation of some; it is more difficult to give and takes longer than a spinal but if only the 2nd sacral foramina are injected in addition to the caudal canal, as is the case usually for rectal operations, the injections are not very difficult. It is very safe as the anaesthetic solution remains extra-dural; it affords a well-relaxed, well-anaesthetized field.

Avertin as a basal or preliminary anaesthetic continues to receive some condemnation but more favorable reports. Evipal given intravenously appears to be especially indicated where a short anaesthetic, of 15 to 20 minutes duration suffices. Newer drugs have been tried in infiltration anaesthesia. The use of diothane in 100 anal cases is reported by *Rosser*. He found it gave anaesthesia enduring "several, to 24 hours," the results were not uniform, a tendency to skin tag formation following its use is noted. A few cases had abscess but the use of normal saline solution to replace the distilled water in which the diothane was dissolved, avoided this complication. 1 ounce of either the 1% or 0.5% solution was used.

Bacon used nupercaine in 91 anal operations and summarizes his results thus: it may be used without ill effects,

its initial effect is somewhat slower than procaine but the duration is prolonged by a few hours; in amounts not exceeding 70 c.c. of a 1:1000 solution it may be injected safely and efficiently. Various ointments containing nupercaine, pantocaine and other synthetics, having a more enduring action than procaine or benzocaine have been placed on the market.

No. 1. 1:2—Benzanthracene



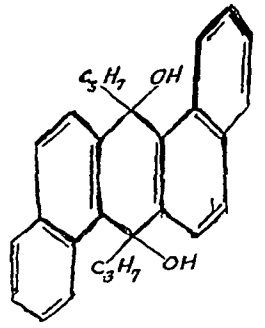
Frankfeldt in Yeoman's Clinic states he has used nupercaine in Gabriel's formula in 150 cases in a 2 year period and found it valuable. The solution is made up of 0.5% nupercaine base, 10% benzylalcohol, 1% phenol in rectified almond oil. It is not used in the ordinary hemorrhoidectomy but has its field in external thrombotic hemorrhoids, pruritus ani, fissure, short fistulae, and anal neuroses.

CANCER

Progress: In the last two years a correlation has been made of some previous and much recent data in the field of cancer research. It has been determined that there is a close relationship both chemically and in biologic effect between some of the hydrocarbons in tar and estrogenic hormones. The tricyclic phenanthrene ring system is common to a group of carcinogenic hydrocarbons. Compounds related to 1:2 benzanthracene, which is itself inactive, have been made to produce carcinoma. The principal carcinogenic hydrocarbons thus far found are (1) 1:2 benzpyrene, one of the most active substances; (2) 5:6 cyclopenteno-1:2 benzanthracene; (3) 1:2:5:6 dibenzanthracene; (4) 9:10 dihydroxy-9:10 di-n-propyl-9:10 dihydro-1:2:5:6 dibenzanthracene; (5) 6 isopropyl-1:2-benzanthracene; (6) various other derivatives of 1:2:5:6 dibenzanthracene; (7) chrysene. All of these substances have produced either carcinoma or sarcoma, rats and mice being used principally. These agents do not produce cancer directly as the agent of Rous sarcoma does, but indirectly. Carcinogenic substances similar to those mentioned might conceivably arise from sterols normally present in the body, it has been suggested by *Kennaway* and *Cook*.

"The hydrogenated phenanthrene ring type of compound, as already pointed out, only recently has been recognized as a normal constituent of the body. Mainly through the work of *E. L. Kennaway* and his co-workers at the Cancer Hospital, it has been proved that a carcinogenic agent present in tar also belongs to this particular type of chemical compound.

"The gradual elucidation of the structure of cholesterol, vitamin D, and the sex hormones has increased the theoretical importance of the work of Kennaway and his colleagues, since prior to these investigations it might have been argued that the production of tar cancer (first produced by Yamagiwa and Ichikawa, 1915) was of purely academic interest, as the carcinogenic agents apparently bore no relationship to substances taking part in the composition of the body. Their extensive investigations, however, have shown that the carcinogenic hydrocarbons belong to this form of condensed carbon ring compounds, and as has been pointed out by *Cook*, the processes which would be entailed by the formation of the compounds from the naturally occurring sterols and bile acids would involve reduction, dehydration and dehydrogenation and might readily occur in the animal body; it seems possible that these carcinogenics might result from the processes operating upon degradation products of sterol metabolism." (*Cook*, 1933).



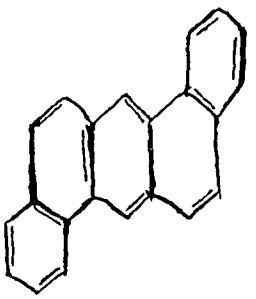
No. 2. 1:2—Benzpyrene

In 1932. Cook, Hieger, Kennaway and Mayneord showed that a series of compounds related to 1:2—benzanthracene possesses carcinogenic properties.

Aschheim and *Hohlweg* determined that in extracts of bituminous material there are estrogenic substances. Recently various investigations have made it probable that "luteal hormones have a similar chemical constitution to the estrogenic hormones."

Cook and *Dodds* and their associates examined a number of hydrocarbons of known carcinogenic character to determine whether they could induce estrus in castrated mice and rats. The first such compound of known chemical structure, which was demonstrated to be estrogenic, is 1-keto 1:2:3:4 tetrahydrophenanthrene. A substance may be both carcinogenic and estrogenic; some that are carcinogenic are not estrogenic, and there are estrogenic substances which are not carcinogenic. Those most active carcinogenically are not the most potent estrogenic compounds.

No. 3. 9:10—Dihydroxy—
9:10—di—n—propyl
9:10—dihydro
1:2:5:6—dibenzanthracene



This is the most potent synthetic oestrus-producing agent, obtained by Dodds and is a derivative of 1:2:5:6—dibenzanthracene, the carcinogenic hydrocarbon.

Lacassagne has induced mammary cancer in male mice by injecting estrogenic material ("folliculine"). Only the secondary sex organs, not other portions of the body, are thus affected by ovarian hormones. This specific character distinguishes the action of ovarian hormones from the carcinogenic agents in tar.

Summarizing (*Leo Loeb*) (1), "the carcinogenic hydrocarbons of tar and related compounds, estrogenic substances as well as certain other factors, may cause cancer in those tissues on which they act, but while carcinogenic hydrocarbons as well as regenerative processes (irritation) may affect a great variety of tissues, the estrogenic hormones are limited in their action to the tissues in which they induce growth processes during the normal sexual cycle. Both the hydrocarbons and hormones mentioned

1. Loeb, Leo: Estrogenic Hormones and Carcinogenesis. *J. A. M. A.*, 104:1597, May 4, 1935.

bring about the cancerous transformations of tissues in an indirect manner. They differ in this respect from other agents merely from a quantitative point of view. The mechanism by which ovarian hormones produce proliferative processes in the sex organs differs from the mechanism underlying the cancerous transformation, although the latter may ultimately depend on proliferative processes

No. 4. 1:2:5:6—Dibenzanthracene

acting over a long period of time. There exist, therefore, no direct but only indirect connections between the carcinogenic action of the hydrocarbons of tar and the carcinogenic effect produced by estrogenic hormones."

The foregoing in a brief and necessarily incomplete way indicates the progress being made in this field. Real additions to the knowledge of cancer have been achieved; whether they constitute an important aggregation of blocks in a puzzle picture or are rather coral accretions in relation to the whole problem time must decide.

General. Both American and European literature contains an increasing number of articles favoring the radical abdomino-perineal operation for rectal cancer. *Kirschner* and *Nemec* report doing both the laparotomy and posterior resection synchronously, two surgeons being employed. Voices are raised however in favor of preliminary colostomy and secondary posterior resections and against extending the indications for the more radical operation. As with other radical procedures for cancer elsewhere, the more radical and effective operation may defeat itself by too high a primary mortality, especially in the hands of surgeons having few rectal cancer cases.

As an outstanding authority in the field, *Rankin's* publications merit careful reading, especially those which appear this year in the American Journal of Surgery; Surgery, Gynecology and Obstetrics, and the Proceedings of the Royal Society of Medicine.

Thomas E. Jones' articles on abdomino-perineal resection are worthy of their author, in whom good surgical judgment is combined with finished operative technic. The symposium on rectal cancer in the American Journal of Surgery has contributions by such authorities as Lynch, Jones, Lahey, Binkley, Yeoman, and Barber.

Diagnosis. Fansler and *Anderson* present clearly the matter of diagnosis in the operable stage of the growth and preoperative and post-operative treatment; their gross description of the types of cancer is informative. *Horsley* notes, forcefully, that attention to slight symptoms makes early diagnosis possible. *Meehling* epitomizes the diagnosis and treatment. *Rosser's* further publications on the relation of chronic inflammatory changes to the development of carcinoma contain data which are definite contributions to his subject. He reports 1 fissure, 4 hemorrhoids, 9 fistulae which have undergone carcinomatous change in 2 to 20 years. *Jelks* regards infection, especially that from streptococci, as an important factor in carcinogenesis.

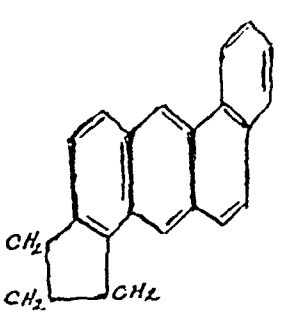
Hayes and Ellis describe the technic of biopsy by needle puncture and aspiration, used in 1400 cases at the Memorial Hospital. Among pathological curiosities and interesting cases noted in clinical reports are the following:

Wakeley reports a case of obstruction from sigmoid cancer with rupture of the cecum.

Jaffe autopsied a case of annular carcinoma of the recto-sigmoid junction with multiple irregular ulcers in the colon above it, which he classified as stercoral ulcers, resulting from the capillary stretching and consequent anaemia in the distended bowel.

Ross' article on carcinoma in youth brings the subject up to date. *Pfeiffer* and *Wood* report a transverse colon cancer in a 7 year old boy.

Smith and *Broders* report 2 cases of melano-epithelioma and 2 of hemangio-endothelioma of the anus; in one of each diagnosis was made only by the tissue examination by the pathologist.



Dixon and *Beaver* report a carcinoma of the rectum treated by fulguration and radium which at autopsy showed no carcinomatous cells in the scar of fulguration and no metastases; death resulted from cerebral embolism. Excised scar tissue in one of *Strauss'* sections shows cancer cells present, in another case they were absent.

Surgical Treatment. Raiford presents an extensive discussion of carcinoma of various segments of the large bowel and reports progress as to operability, 5 year cures and post-operative mortality over a 34 year period; he also reviews the statistics of rectal and anal cancer at Johns Hopkins Hospital.

It seems obvious that no one operation is suitable to all cancers in the middle and upper rectum, to say nothing of those above these sites but still too low for an "obstructive resection" or Miculicz operation, yet this point is lost sight of in some writings.

T. E. Jones continues to favor the one stage radical abdominoperineal resection. *Rankin* prefers the abdomino-perineal method but uses it in two stages perhaps more frequently. Four to six weeks after exploration the colostomy (single barrel) is done, a perineal incision is made to free the rectum up to the peritoneum, the skin closed and laparotomy performed, at which the removal of the rectum and sigmoid is completed. He uses gas-oxygen-ether or ethylene and trans-sacral anesthesia in preference to spinal because of two recent operating room casualties. *Dixon* favors the abdomino-perineal (Miles) procedure where the cancer site permits a choice of method in the higher grades of malignancy, and posterior resection after colostomy for the less malignant growths.

Lahey continues to use his method of fixing the end of the distal segment of the bowel in the abdominal wall, in the midline above the bladder.

No. 5. 5:6—cyclo-Penteno—
1:2—benzanthracene

Gordon-Watson emphasizes the effects of surgical experience on the percentages in operability and mortality statistics. *Gabriel* reports a 20% mortality in 25 one stage abdomino-perineal excisions of the rectum. He restricts perineal excision to very early or very advanced carcinomas of the anus and lower third of the rectum.

Finsterer, O. Goetze, H. Schneider, H. Voelker, M. Kirschner among other Europeans favor abdomino-perineal operation in one or two stages.

Lockhart-Mummery and *H. van Seeman* among others favor preliminary colostomy and secondary posterior resection. *M. Lichtenauer* advocates perineal excision of rectum without colostomy.

The importance of *preliminary preparation* and after care is repeatedly emphasized, viz: (1) Blood transfusion often advisable before operation, more frequently afterward.

(2) The establishment of a satisfactory water balance especially in the dehydrated patient.

(3) The relief of hypoglycemia by free sugar intake.

(4) Evacuation of bowel pre-operatively (repeated enemas; if obstruction absent, cautious catharsis).

(5) Pre-operative opiate medication to quiet peristalsis.

(6) Careful cleansing of the lower loop before second stage of two stage operation.

(7) Some method of peritoneal vaccination is used by a number of surgeons; its value is questioned by others.

Irradiation Therapy. Irradiation treatment continues a palliative measure but as radiosensitivity and dosage become better known the indications for its use as a curative agent are advanced by some experienced therapists. *Bowing* and *Fricke* report 500 cases and feel that the higher grades of malignancy especially, require irradiation.

The British Medical Journal Annotations note that low voltage X-ray therapy as used by *Chaoul* in Germany may obtain results to compare favorably with the radium bomb. *Binkley* records his results with a technic consisting of pelvic radiation with a maximum skin dosage through 6 or 7 portals of entry, given daily for 3 weeks. In proper cases 1-3 millicuries of gold screened radon needles are implanted per rectum, 2 weeks later. Further treatment is advisable at a later period in some cases. Palliation only is sought in the advanced (inoperable) cases; curative results may ensue in the selected early cases.

Max Cutler states the decision between operation and irradiation is at times difficult, such decision is based on 2 factors: operability and radiosensitivity. The clinical signs of operability are often fallacious, the extent of the disease may be impossible to determine by clinical examination. Radiosensitivity does not necessarily mean curability nor (to a less extent, Ed.) does radioresistance mean incurability.

Electrocoagulation. Strauss used electro-coagulation of the tumor in 42 patients, 20 having a colostomy done. He feels the results justify the continuance of this form of treatment. He states the results compare favorably with radical excision and half of the group escaped a colostomy.

Thorek states that inoperable cases may be benefited and life prolonged by electro-coagulation of the tumor and proctotomy.

Chemotherapy. Bargen concludes that colloidal lead phosphate given intravenously to a degree of lead intoxication possesses value.

Murray gives a critical review of the selenide treatment of cancer. *Körbler* in Germany and several South American authors favor the use of snake venom for its inhibitory effect on cancer and especially to relieve pain. Others deny its value.

To those who wish to follow the subject of cancer closely the Abstracts in the American Journal of Cancer; and Surgery, Gynecology and Obstetrics will prove valuable.

SECTION VIII—*Editorial*

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastroenterological Association is in no way responsible for editorial expressions.

CERTAIN PERTINENT OBSERVATIONS UPON MILK AND CHOLESTEROL AS THEY RELATE TO INFECTION AND TO ARTERIOSCLEROSIS

SINCE the publication of my review on "Milk" (*) as well as the editorial on "Cholesterol" (**) in this Journal, developments of such importance have occurred that I am impelled again to direct attention to these topics.

MILK

First, I wish to emphasize the tremendous consequences of the *infectious elements that are carried by milk.* Prof. Lloyd Arnold (1) believes that I am unduly alarmed about the milk problem and that pasteurized milk is safe and wholesome. He calls attention to the fact "that the dorsum of the tongue contains a rich endogenous bacterial flora and that sterile milk will not be sterile when it passes through the oral cavity." Why then should we not continue to feed raw milk and not trouble to pasteurize it, or bother about infectious elements carried in other foods? No, like all milk bacteriologists, Dr. Arnold relies upon the *total* bacterial count and has the ideal of pasteurization constantly before him. Pasteurization at best is but an ideal procedure. Dr. Arnold realizes that it is rarely carried out as planned or theoretically considered proper. Even when so conducted, pasteurization does not kill all the pathogenic bacteria. This has been well demonstrated in the epidemic of bovine tuberculosis in Great Britain, where "over the counter" milk was found frequently to be contaminated. *It is imperative that the bacteriologist follow this method of examination and study the milk for pathogenic bacteria as it comes to the consumer.*

However, Dr. Arnold's contribution revealing the bacterial content of the lingual mucosa is of great value. The tongue may act as a focus of infection. It is a rule in my Clinic to advise swabbing the tongue with a ten per cent mercurochrome solution during the treatment of infectious diseases particularly of ulcerative colitis, gastric and duodenal ulcer, gall bladder disease, etc.

As an illustration of the tremendous influence of the propaganda for the increased consumption of milk, I cite the fact that two bacteriologists whom I attempted to induce to engage in the bacteriologic study

*"Milk"—Horace W. Soper, M.D.: *Am. Jour. Dig. Dis. and Nutr.*, Vol. 11, No. 2, p. 113.

**"Cholesterol"—Horace W. Soper, M.D.: *Am. Jour. Dig. Dis. and Nutr.*, August, 1935.

of milk as it is received by the consumer, refused to do so on the grounds that they would do nothing that might impair the confidence of the public in milk as a food!

G. M. Fyfe (2), health officer for St. Andrews, England, in his annual report, says that about forty per cent of the cows in that country are infected with tuberculosis. Scoville (3) states that mild ambulatory cases of *Brucella abortus* infection in man are common and frequently not diagnosed. Angle (4) calls attention to the tremendous increase of *Brucellosis* in this country. He finds that 9965 cases were reported to January, 1935, and concludes that the correct diagnosis is never made in many of the cases.

Minnett (5) discusses *"the widely prevalent and well recognized chronic form of streptococcus mastitis existing in our herds"* and directs attention to an acute streptococcus mastitis of such severity that partial destruction of the udder occurs. Swift, Langfield and Goodner (6) present a table of the various groups of hemolytic streptococci. In their Group "A" they refer particularly to cattle affected with mastitis and to the human infections, such as scarlet fever, puerperal sepsis, erysipelas, septic sore throat, pneumonia, etc. They state, "When, therefore, members of (the hemolytic streptococci group) are found in milk, the inference to be drawn is either that the cows furnishing the milk have mastitis due to a Group A streptococcus, or that the milk has become contaminated from a sick man or from a human carrier. It seems probable, therefore, that any milk in which Group A hemolytic streptococci are found is unfit for human consumption. Probably the presence of strains other than Group A in the throat, intestine or vagina of human beings arises from the consumption of milk or other food products containing them."

Geiger, *et al* (7), in "Food Poisoning from Ice Cream," conclude that "since the lower temperatures used in ordinary refrigeration and ice-cream freezing have only growth-*inhibiting* and not bacteria-*destroying* power, and since milk and milk food products, because of their inherent character, offer excellent bacterial culture medium possibilities, ice-cream and other milk food products should be subject to rigorous standards in production, processing and marketing, with the provision of every reasonable safeguard to the public health."

The above facts cannot be dismissed with a wave of the bacteriologic hand and the statement that "the organisms found were not proved to be pathogenic for man." Clinical experience teaches us that the canned evaporated milk is safe, contains all the essential nutritive elements, and cannot remain on the dorsum of the tongue long enough for propagation of the bacteria.

Clinicians are not concerned about the 75% or 90% of individuals who establish an immunity against streptococcus or tuberculous infection, but *are* interested in the smaller percentage of mankind who are susceptible. Milk is undoubtedly the chief agency for the dissemination of the streptococcus. Where did *this* case of *S. viridans* originate? Why does such a large percentage of school children develop infected tonsils? Where did *this* patient acquire septic sore throat? Why is the increase of dental caries in children concomitant with the augmented consumption of milk? Such are questions constantly arising in practice; they require definite answers.

Probably man has employed milk as a food for over 6000 years according to his drawings on cave walls. His use of the herd unquestionably marked the dawn of community life and laid the foundations of modern civilization.

Since the vitamine theory originated by McCollum, the propaganda for the larger use of milk in our dietary has been so active that nearly all students of nutrition are obsessed by it. What are the biological inferences?

1. All mammals, excepting the human, cease the use of milk as a food after weaning. The mother's mammary gland remains quiescent until activated by parturition.

2. The dairy cow, stimulated and bred to yield milk over a long period of time, develops hypertrophy of the mammary gland. She is frequently found to be infected with a low grade streptococcus mastitis. Efforts to disinfect the udder often cause a chronic eczema; crusts and scales fall into the milk.

3. Milk is such a good culture medium that it is frequently contaminated by infectious agents not originating in the cow. "Bacterial soup" is a good synonym for milk.

4. As a result of his violation of a primary biologic law, Man has been severely penalized by the host of infectious diseases that are disseminated by milk.

I am aware of the magnitude of the problems involved and my object in this presentation is to stimulate further study and criticism of milk as it reaches the consumer.

CHOLESTEROL

In my first communication, I directed attention to the clinical significance of the subject, relying especially on the work of Leary (8), Joslin (9), Rabinowitch (10), Hartung and Brüger (11), Lockie and Hubbard (12). Since that time numerous important contributions have been made to the current literature.

Moschcowitz (13) contests the theory of the metabolic origin of arteriosclerosis. He asserts that simultaneous arteriosclerosis in the pulmonary and general circulation rarely occurs and that the relation of intravascular tension in the causation of arteriosclerosis is vital in the study of the problem.

In reply to Moschcowitz, Leary (14), states that he has shown that the lesions of human atherosclerosis owe their variety to the relative ability of the cells in these lesions to metabolize cholesterol. In youth this power is great, in middle life the metabolism is slow and scarring results. In old age, the cells cease to function and "atheromatous abscesses" are responsible for the selective localization and degree of the lesions. Basically, atherosclerosis is dependent for its causation in disturbances in the cholesterol metabolism.

Joslin, Warren and Root (15) also reply to Moschcowitz, taking exception to his statements "that all evidence seems to show that arteriosclerosis is the cause of diabetes rather than the reverse," and "when diabetes occurs in arteriosclerosis, the inference is that the capillaries of the islands of Langerhans are affected." They point out that at least 10% of all cases of diabetes begin in the first two decades of life without any evidence of the existence of arteriosclerosis and that persons with diabetes of long duration show more arteriosclerosis in the legs and heart than do

non-diabetic persons. Many cases of diabetes at autopsy show little or no arteriosclerosis of the pancreatic vessels even though vascular damage elsewhere is severe.

Brenner (16) states "that pulmonary vascular sclerosis increases in frequency and severity with the age of the patient. It is practically as common as systemic vascular sclerosis and is constant in patients over forty."

Many clinical articles, too numerous to mention here, have appeared recording the good effects produced in vascular disease by a sharp limitation of the cholesterol content of the diet. I personally can confirm the good results produced by this method even in advanced severe cases of vascular disease affecting the cerebral and coronary vessels. For years I employed an "alkaline ash" regimen, which was in reality a diet with small cholesterol content. Sansum, in a personal communication, states that his clinical experience has been identical with mine when employing the same dietary regimes. Space forbids publishing case records here but I hope to do so in the near future. Such dietary formulae are not easy to follow. The whole art of modern cookery is in a conspiracy against it. The chief articles to avoid are eggs, cream, butter, pork fat, and the solid internal organs, as liver, sweetbreads, etc. Nearly all muffins and desserts are milk, cream, butter and egg concoctions.

Experimental work in cholesterol metabolism has demonstrated the great value of thyroid as well as iodine as controlling agents or lipoid solvents. I can verify the efficacy of their employment, clinically, in selected cases.

The evidence appears to justify the statement that hypothyroidism is usually associated with a poor cholesterol metabolism, which would account for the tendency of individuals of this type to develop *obesity, gall stones, gout, degenerative arthritis* and *cataract.*

More chemical work on food stuffs is necessary particularly in regard to the vegetable oils. More intense clinical study is highly desirable so that we may control the intake of cholesterol with more exactness.

We know that cholesterol is a necessary constituent of the body cells, but enough evidence has accumulated to the effect that an excess in the diet may be extremely injurious especially to the adult after fifty.

The clinician of today should be both milk minded and cholesterol conscious, not only in the treatment of disease but in the realm of Preventive Medicine.

Horace W. Soper, St. Louis.

Program of the Thirty-Ninth Annual Meeting of the American Gastro-Enterological Association

MAY THE 4TH AND 5TH, 1936
HOTEL CLARIDGE
ATLANTIC CITY, N. J.

MONDAY, MAY 4, 1936

MORNING SESSION, 9:00 A. M.
Daylight Saving Time

MEMORIAL ADDRESSES
of

Dr. John Bryant by Dr. Franklin W. White
Dr. Lafayette B. Mendel by Dr. Victor C. Myers
Dr. Henry W. Bettmann by Dr. Leon Schiff
Dr. George W. McCaskey by Dr. William Gerry Morgan

PRESIDENTIAL ADDRESS
Dr. Howard F. Shattuck, New York, N. Y.

1. "Cholesterol Metabolism in Jaundice"
   Dr. S. Allen Wilkinson, Boston, Mass.
   Discussion to be opened by Dr. Andrew C. Ivy, Chicago, Ill.

2. "Biliary Stasis"
   Dr. Carl H. Greene, Brooklyn, N. Y.
   Dr. J. Russell Twiss, New York, N. Y.
   Dr. R. Franklin Carter, (by invitation), New York, N. Y.
   Discussion to be opened by Dr. Charles Gordon Heyd, New York, N. Y.

3. "The Prognosis of Acute Hepatic Insufficiency"
   Dr. Chester Jones, Boston, Mass.
   Discussion to be opened by Dr. H. L. Bockus, Philadelphia, Pa.

4. "Chronic Hepatitis with Jaundice (Biliary Cirhosis)"
   Dr. James F. Weir
   Dr. Albert M. Snell, Rochester, Minn.
   Discussion to be opened by Dr. David Riesman, Philadelphia, Pa.

5. "Macrocytic Anemia in Diseases of the Liver"
   Dr. David H. Rosenberg, Chicago, Ill.
   Discussion to be opened by Dr. M. M. Wintrobe, (by invitation), Baltimore, Md.

THE ALVAREZ LECTURE

Founded in 1929 by Dr. Frank Smithies

"THE DIGESTIVE TRACT IN ANEMIA"

Dr. George R. Minot, Professor of Medicine, Harvard University, Boston, Mass.

Adjournment for Luncheon

2:30 P. M.

6. "Miscellaneous Observations on Intubation of the Small Intestine"
   Dr. T. Grier Miller
   Dr. W. Osler Abbott
   Dr. Walter G. Karr, (by invitation), Philadelphia, Pa.
   Discussion to be opened by Dr. Max Einhorn, New York, N. Y.

7. "Surgical Aspects of Regional Ileitis"
   Dr. A. A. Berg, New York, N. Y.
   Discussion to be opened by Dr. Sara M. Jordan, Boston, Mass.

8. "The Components of Gastric Secretion"
   Dr. Franklin Hollander, (by invitation), New York, N. Y.
   Discussion to be opened by Dr. Walter C. Alvarez, Rochester, Minn.

9. "Gastric Secretory Behavior in Chronic Gastritis"
   Dr. H. L. Bockus
   Dr. J. F. Monaghan, (by invitation)
   Dr. Karl Kornbloom, (by invitation), Philadelphia, Pa.
   Dr. George R. Moffitt, (by invitation), Harrisburg, Pa.
   Discussion to be opened by Dr. Burrill B. Crohn, New York, N. Y.

EXECUTIVE SESSION

(Associate members are requested not to attend)

ANNUAL DINNER, 7:30 P. M.

HOTEL CLARIDGE, ATLANTIC CITY, N. J.

Guest of Honor

Dr. William Mather Lewis, President, Lafayette College, Easton, Penn.

"The Cultural Background of the Professional Man in Medicine"

TUESDAY, MAY 5TH, 1936

MORNING SESSION, 9:30 A. M.

10. "Further Experimental Studies on the Etiology of Ulcerative Colitis: The Possible Virus Factor"
    Dr. Moses Paulson, Baltimore, Md.
    Discussion to be opened by Dr. Heinrich Necheles, Chicago, Ill.

11. "The Diagnostic Significance of Anti-Dysentery Bacteriophage"
    Dr. T. T. Mackie, New York, N. Y.
    Discussion to be opened by Dr. Morris L. Rakieten, (by invitation), Brooklyn, N. Y.

12. "Symposium on the Pancreas"
    Physiological Aspects: Dr. Andrew C. Ivy, Chicago, Ill.
    Pathological Aspects: Dr. William G. MacCallum, (by invitation), Baltimore, Md.
    Medical Aspects: Dr. Thomas R. Brown, Baltimore, Md.
    Surgical Aspects: Dr. Daniel F. Jones, (by invitation), Boston, Mass.
    Discussion to be opened by Dr. Joseph H. Pratt, (by invitation), Boston, Mass.

13. "Report of Special Committee on Enzymes"
    Dr. A. H. Aaron, Chairman, Buffalo, N. Y.

Adjournment for Luncheon

2:00 P. M.

14. "Hypoglycemia—A Clinical Survey of Four Hundred Cases Having This Common Finding"
    Dr. Lay Martin, Baltimore, Md.
    Dr. George A. Hellmuth, (by invitation), Baltimore, Md.
    Discussion to be opened by Dr. Victor C. Myers, Cleveland, Ohio.

15. "Thoracic Stomach and Diaphragmatic Hernia"
    Dr. Leon Bloch
    Dr. A. M. Serby, (by invitation)
    Dr. Samuel Salinger, (by invitation), Chicago, Ill.
    Discussion to be opened by Dr. Dewitt Stetten, New York, N. Y.

16. "Specific Food Sensitiveness"
    Dr. Walter Alvarez, Rochester, Minn.
    Discussion to be opened by Dr. Arthur F. Coca, (by invitation), New York, N. Y.

17. "A Consideration of Some of the Newer Methods for the Treatment of Peptic Ulcer"
    Dr. Andrew B. Rivers, Rochester, Minn.
    Discussion to be opened by Dr. Walter L. Palmer, Chicago, Ill.

8. "Ulcerating Gastric Neoplasms and Their Differentiation from Simple Benign Ulcers, Roentgenological and Pathological Criteria"
Dr. Lewis Gregory Cole, New York, N. Y.
Discussion to be opened by Dr. Frank W. Konzelmann, (by invitation), Philadelphia, Pa

The following papers will be read by title.

"Studies in Gastric Pepsin"
Dr. Frances R Vanzant, Houston, Texas.

"Cystadenomata of the Pancreas: A Surgical Report"
Dr. R. Franklin Carter, (by invitation), New York, N. Y.
Dr. Lewis Slattery, (by invitation), New York, N. Y.

"The Changes Within the Cells of the Gastric Mucosa During Secretory Activity"
Dr. A. J. Gitlitz, (by invitation), New York, N. Y.
Dr. W. Levison, (by invitation), New York, N. Y.

IN MEMORIAM

Ivan Petrovich Pavlov
1849 — 1936

AFTER a full lifetime of extraordinary scientific achievement, and having recently been the central figure of the International Neurological Congress in London and the International Physiological Congress in Leningrad and Moscow, Ivan Petrovich Pavlov died on February 27, at the age of 86.

A photograph of Pavlov taken August 8, 1935.

He was born on September 26, 1849, the son of a poor priest. Being led to abandon a theological education by the stimulus of G. H. Lewes' *The Physiology of Common Life*, he entered the University of St Petersburg (1871) and there came into contact with von Cyon, a brilliant thinker and an expert in physiologic methodology, and the talented chemist Mendeleef. He became a collaborator with Cyon in 1874 and an assistant in 1875 under whom with Afanasiev he did his first investigation on the pancreatic nerves. After completing the medical course in the Military Academy in 1878 or 1879, he was granted a fellowship in the research laboratory of Botkin, an internist, which enabled him to continue in research and to complete his thesis for the M.D. degree in 1883. His thesis described, independently of Gaskell, the nervous control of the heart. He then studied for two years (1884-86) under the Wylie fellowship with Ludwig and Heidenhain in Germany. On returning to St Petersburg he again worked in Botkin's laboratory, his chief research interest from 1878 to 1888 being the circulatory system. In 1890 he was appointed Professor of Pharmacology at the Military Medical Academy in St. Petersburg, a position he retained until 1924 However, in 1891 he was also appointed director of the department of physiology in the newly built Institute of Experimental Medicine where he started and did most of his work on the digestive glands and had the opportunity of taking full advantage of the recently developed technique of aseptic surgery and of making a detailed exploration of the gastro-intestinal tract by the production of "chronic" fistulae in animals. His classical monograph, *The Work of the Digestive Glands*, appeared in 1897 and constitutes, figuratively, the "Old Testament" of digestive physiology. The English edition, which appeared in 1910,

represents the research achievements of Pavlov and his entire laboratory staff from the period of about 1888 to 1904. For this work he undeniably merited and received the Nobel prize in 1904. In 1902 being impressed by his observations on the "psychic" secretion of saliva, gastric and pancreatic juice, the direction of his research changed. Subsequently, he devoted his entire attention to a study of processes in the central nervous system by the method of conditioned reflexes.

It is idle to review those magnificent studies on the higher reflex mechanisms which are so well known and which form the groundwork of any comprehension of central nervous system activity. And, a further appreciation can add little to his dominant and secure place as one of the foremost benefactors of science and human endeavor. Pavlov, the man, was characterized by a single minded devotion to his science. During the rigors of the revolution, when without heat or light, his only complaint was of having to spend six hours each day guarding the firewood stacked outside the Academy. He was no stranger to hard work. In his earlier experiments the operated animals were tended by his wife and himself in their own home. A man of great intellect, scientific honesty, and gentlemanly simplicity, it is fortunate for the world that he was permitted a long and useful life.

Northwestern University, Chicago.

SECTION XII—*"The Clinic"*

Gastric Carcinoma

Necessity for Earlier Diagnosis as Shown by Case Reports

By

B. MARKOWITZ, M.D.
BLOOMINGTON, ILLINOIS
and
M. D. MOLAY, M.D.
CHICAGO, ILLINOIS

CARCINOMA of the stomach is one of the most frequent offenders in producing a discrepancy between the pathological and clinical findings. Often the history indicates a gastric upset dating back only 3 or 4 weeks and at operation an extensive inoperable carcinoma is found. The contradictory findings may in many instances be explained by the following: 1. Early gastric cancer does not give the classical symptoms characteristic of the disease as described in text books and 2.—the great variety of forms in which gastric carcinoma presents itself is not made sufficiently familiar to the average physician. MacCarty[1] reports that not over 25% of the gastro-intestinal cancers coming to the Mayo Clinic had previously been X-rayed and 75% of these cases are inoperable and hopeless when first seen at the clinic. In a small series of gastro-intestinal malignancies we[2] have previously reported 70% so far advanced that only biopsy and palliative surgery could be done.

"CLASSICAL" SYMPTOMS

Classical symptoms such as constant and definite pain, constant motor function incompetency, and definite palpable tumor mass are frequently absent and certainly lose their classical distinction, if a series of gastric cancers is studied.

It is the common opinion that pain is constant, dull and aching in type; yet frequently we receive a half or even more than one-half of a resected malignant stomach in which the history of pain was not of the orthodox dull and aching type or paradoxically enough may have been completely absent. Gaither[3] in reviewing 245 cases of gastric cancer comes to the conclusion that there is no characteristic cancer pain and he feels that a consideration of the character of pain is of negligible importance.

Constant motor function incompetency would strangely enough be a highly desirable finding. In the greater number of instances it means a certain degree of pyloric block, which if the progress is rapid, would force the patient to seek early medical advice. Unfortunately, however, we often receive a carcinoma involving a large part of the stomach and the history reveals that there was no motor function incompetency. This is especially true when the tumor involves those areas in which the passageway is not directly obstructed as the cardia or the lesser curvature. In addition there is the infiltrating type of carcinoma which invades the submucosa and deeper structures and involves most of or all of the stomach with no obstruction. On the other hand, benign polyposis of the stomach may produce a motor function incompetency. The question may be raised, "How often do we find carcinoma associated with polyposis of the stomach?" Benedict and Allen[4] report adenomatous polypi of the stomach as potential malignancies in 41% of the cases, while Jaffe[5] reports that in 100 cases

Submitted November 11, 1935.

of gastric carcinoma autopsied only 7 revealed polypi. He adds however "It is possible, however, that as the tumor grows the polypi are enveloped in the overgrowth and thus obscured."

Similarly we cannot lay too much emphasis upon the presence or size of a definite tumor mass. In certain cases physical and X-ray examination fail to reveal the presence of carcinomatous lesions especially those in the cardia which are later found at operation or post mortem. In other instances the interpretation of the size of the lesion does not correspond favorably with the actual tumor mass found. Nor can the type of onset and time of existence of such a tumor be placed in any definite category. In going over the histories of many of these cases in which large gastric carcinomas were resected, one can easily be convinced that it is possible for such a cancer with ulcer type of history to have existed as a primary malignancy for three to five years. Neither is it difficult to believe that the symyptoms in such cases may be sudden in their onset. Not infrequently we examine a pathological specimen of a large resected gastric carcinoma, the history of which indicates an abrupt rather than a gradual onset.

Just as the time element may be irregular in diagnosis so may the recurrance of such a tumor be irregular in prognosis. The histological structure cannot always settle the prognosis as well as it does the diagnosis. Even the diagnosis of a very early carcinomatous degeneration of an ulcer can be missed and surely the question of recurrence cannot often be definitely settled by the microscopical picture. We have all seen rather malignant forms of cancer which did not recur or recurred after a lapse of years while malignancies of lesser degree recurred rather early. It happens much too often that after a long period of belief in a cancer cure, recurrence is found.

VARIETY OF FORMS OF GASTRIC CANCER

The forms of gastric cancer pertinent to this discussion are those which do not follow the orthodox course as described in text books; particularly those cases in which the symptoms do not point definitely to a gastric disturbance and the diagnosis is established at post mortem examination. Stebbins and Carns[6] recently described a case of thrombocytopenic purpura associated with adenocarcinoma of the stomach in a young adult in which the carcinoma was neither suspected nor found until post mortem examination. In this case the age, too, is somewhat unorthodox; although untold numbers of gastro-intestinal cancers of the young have been reported, yet it is necessary to call the general practitioner's attention to the fact that malignancies of the stomach and intestines not infrequently occur in the young adult notwithstanding the cancer-age spoken of in text books (7).

CASES

The following case histories illustrate the various forms of gastric carcinoma which present symptoms of other ailments:

Case I: A white male, 51 years of age, complained of general abdominal discomfort and vague epigastric pain over a period of 8 months. Occasionally he was nauseated and vomiting gave some relief. His appetite was poor and he had lost 20 pounds during the past 3 months.

On *examination* he was somewhat emaciated and his skin was pale and somewhat sallow. The heart and lungs were negative; the liver was not palpable, the spleen was slightly enlarged; he ran a continous low grade temperature between 99° F. and 99.8° F.

Laboratory examination revealed: R.B.C. 1,920,000; W.B.C. 4,500; Hemaglobin 48%; marked poikilocytosis and disproportion in size of red cells many of which were more than twice the normal size; no immature forms were found; *icteric index* was reported as 10; *Benzidine test* on stools strongly positive; an Ewald test meal showed 48° total acidity and 18° free hydrochloric and positive occult blood test. *X-ray examination* was negative except for the suggestion of a decreased pyloric diameter; this was not considered a deformity.

The *clinical diagnosis* rested between a primary anemia and carcinoma of the stomach. Despite transfusions, liver therapy and supportive measures, the patient ran a very rapid down-hill course and died 10 months after the onset of complaints.

At post mortem one was immediately struck with the pale anemic appearance of all the organs. The heart was normal in weight (305 grams) and in appearance. The lungs were congested, otherwise normal. The spleen was slightly enlarged, (205 grams) soft and the pulp was purple red. The liver appeared normal (2,000 grams). The essential findings were in the stomach. Its walls, especially at the pyloric end were thick and leathery, the cut surface was light gray and gristle-like. The mucosa was pale and with the exception of several small plaques in the pre-pyloric region, quite smooth. The perigastric lymph glands were all enlarged, firm and gray. *Microscopic examination* of the stomach wall and lymph glands confirmed the gross diagnosis of a scirrhous carcinoma.

The combination of symptomless carcinomas of the stomach and severe anemia is not infrequently found at the post mortem table. Such anemia may even present hematological findings of pernicious anemia and in the absence of definite gastric symptoms may present the picture of a primary anemia (7).

Case II. A well developed, rather obese female, 41 years of age, gave the history of having been entirely free from any digestive disturbance up until two months before examination. At that time she was seized with sudden cramp-like pain in the "pit of the stomach" which lasted several hours and was followed by a spell of vomiting and diarrhea. Since this first onset she had had two or three milder attacks neither of which was very severe. Vomiting however occurred quite frequently and the pain was described as "just everywhere over the abdomen."

On *examination* the temperature was elevated about one degree, the skin was slightly icteric and a tender mass was palpable in the middle upper abdomen just to the left of the midline. The liver and spleen were not palpable and all other findings were negative. Laboratory examination revealed 18,500 W.B.C. with 72% polynuclear cells, an icteric index of 22 and an Ewald test showed 42° total and 22° free hydrochloric acid. *Upon X-ray examination* there was an unexplained defect in the cardia of the stomach. Negative findings in the intestines and "no visualization" of the gall bladder were reported.

The patient was considered a surgical case with ruptured gall bladder and retrogastric abscess or pancreatic abscess as the most likely diagnosis. At operation a large abscess was found in the lesser peritoneal cavity. Despite drainage and supportive measures including transfusions the patient died on the third post operative day. At post mortem examination the essential pathology was an ulcerating adenocarcinoma of the greater curvature of the stomach which had perforated through the meso-colon with abscess formation.

Cancers of the cardia of the stomach are comparatively rare (about 10%) and are rather difficult to diagnosis. Found in this area, which is termed a

silent area, the lesion produces very few symptoms because no obstruction results.

CONCLUSIONS

In reviewing any large number of cases it will be found that early cancerous lesions of the stomach present no typically definite symptoms and that those listed in our books are those exhibiting symptoms of advanced malignancy; that gastric carcinoma at times manifests itself in atypical forms. For these reasons it is necessary to revaluate the symptoms and clinical histories for teaching purposes. Such teaching that symptoms are always gradual, that pain is always constant and dull, that a mass is always palpable, that weight loss is an extremely important factor and that there is a definite cancer age should be modified in face of repeated contradictory post mortem findings. Instead, stress should be placed upon finding the early gastric cancer by suspecting every case of continuous gastric distress as a potential malignancy until proved otherwise.

ABSTRACTS

CLINICAL MEDICINE

JONES, CHESTER M., BENEDICT, E. B., AND HAMPTON, A. O.

Variations in the Gastric Mucosa in Pernicious Anemia: Gastroscopic, Surgical and Roentgenologic Observations. Am. Jour. Med. Sci., Nov. 1935, p. 596.

Apparently there are histologic changes in the gastric mucoca which are invariably associated with pernicious anemia. These changes consist in a diffuse inflammatory process leading to atrophy of the gastric glands, most striking in the cardia and decreasing in severity toward the pyloric end of the stomach. Henning is quoted as having found diffuse atrophy of the mucous membrane in all cases of pernicious anemia, in many cases of complete achylia and carcinoma of the stomach. The color of the mucous membrane is grayish yellow or grayish green. (The color of normal gastric mucous membrane is red) (the Authors' note).

The purpose of the authors was to study the stomach mucosa endoscopically during relapses and remissions in pernicious anemia and contrast the two. Five cases are reported in complete and exhaustive detail. One during his illness had a gastric hemorrhage and at operation a small adeno-carcinoma of the greater curvature was found and removed. The man recovered and gastroscopy in March 1935 showed slight hypertrophy of the mucosa without polypus or metastases.

Patient 2 had pernicious anemia with gallstones which were removed together with two polypoid tumors of the stomach. Hypertrophic gastritis was found. The operation was done during a remission following intensive parenteral liver therapy. The polypi which were removed were subsequently pronounced adeno-carcinoma. Two months later the patient was vastly improved and gastroscopy showed a mucous membrane of normal color with apparently normal gastric markings.

Patient 3 was diagnosticated as pernicious anemia and X-ray showed an irregular filling defect in the lower half of the stomach which was thought to be carcinoma. The gastric contents with histamine showed anacidity. Gastroscopy showed a very pale, thin mucous membrane throughout the entire stomach. On the lesser curvature and posterior wall of the antrum there was a rounded elevated red tumor which on later operation was found to be a long polyp ulcerated in two places. It was benign. The patient convalesced but later relapsed because his treatment was not continued. Gastroscopy revealed a chronic gastritis. Treatment for pernicious anemia was re-established and two months later gastroscopy showed a mucosa which was of normal color with no apparent atrophy.

Patient 4, a woman, aged 70, showed gastric contents with some blood and no free HCl. A diagnosis of pernicious anemia and gastric polyposis was made. At operation several months later when her R.B.C. count was 5,500,000 and hgb. 90%, the mucosa of the stomach was found covered with small polyps; one three inches in diameter. Six years later the patient felt well on the ingestion of liver and gastroscopy revealed what was thought to be nearly a normal appearance of the stomach.

Patient 5, white man, aged 46 was found with pernicious anemia and a pale gastric mucosa of an atrophic gastritis with probable pseudo-polyposis. Intensive liver therapy was instituted and two months later the color of the gastric mucosa was practically normal, though somewhat granular in places. On the greater curvature there was a small smooth swelling which might have been a polyp.

The authors found by repeated examinations of the gastric contents in the patients exhibiting improved mucosal conditions under treatment that there was no return of hydrochloric acid where previously achlorhydria had been present.

In the summary of this admirable publication the authors state that following specific therapy of the pernicious anemia evidences of atrophy and hypertrophy of the stomach have both tended to disappear, and that the change from an appearance of atrophy represents an epithelial change associated with successful treatment of a specific deficiency state, rather than the healing of a chronic inflammatory process; whereas a return to normal from a grossly hypertrophic condition of the gastric mucosa represents a subsidence of a chronic gastritis.

Allen Jones, Buffalo

INGEGNO, ALFRED P.

The Elevated Blood Urea of Acute Gastro-Intestinal Hemorrhage and its Significance. Am. Jour. Med. Sci., Dec. 1935, p. 770.

Forty-two cases of hemorrhage due to peptic ulcer are reported and the cases divided into two groups—1, including 17 cases with blood urea of over 38 mgms. and another group of 25 cases with blood urea less than 38 mgms. There were no deaths in either group. Neither sex nor age seemed significant nor was there noticeable correlation between the azotemia and the degree of anemia present. High blood nitrogen figures were almost exclusively found in those in whose blood

samples were taken within three days of the acute episode.

High blood urea nitrogen probably depends upon sudden loss of blood, shock, dehydration and the absorption of nitrogen from the blood in the gastrointestinal tract.

The azotemia probably plays little part in the clinical symptomatology in uncomplicated cases. In cases with hepatic cirrhosis, diabetes or nephritis gastrointestinal hemorrhage may precipitate a very serious or fatal syndrome.

The author concludes:

1. In cases of acute gastrointestinal hemorrhage studied within three days of the occurrence of the hemorrhage, there is an elevation of the blood urea above normal. This is probably due to the nitrogen intake represented by the protein of the blood retained in the gastrointestinal tract, plus the factors of hemorrhage, per se. shock, dehydration and starvation.

2. In complicated cases this azotemia does not reach uremic proportions and plays little, if any, part in the symptomatology.

3. In cases with continuing hemorrhage the elevated urea persists or increases and points to an unfavorable outcome.

CROHN, BURRILL B., AND ROSENAK, BERNARD D.

A Combined Form of Ileitis and Colitis. J. A. M. A., Jan. 4, 1936, Vol. 106, p. 1.

Granulomatous, ulcerating and stenosing inflammation of the small intestine was described by Crohn, Ginzberg, Leon and Openheimer in 1932, and was called regional or terminal ileitis. Later Harris, Bell and Brunn described an identical process in the jejunum, a jejunitis, or regional enteritis.

Another addition to the aforementioned conditions is now described, namely a terminal ileitis accompanied by a simultaneous inflammatory and ulcerative colitis. The clinical manifestations of this disease, which usually occurs in young people, are abdominal pain, nausea and vomiting, mild diarrhea with occasional bloody stools, loss of weight, night sweats and fever going as high as 103 degrees F.

In all the cases presented, there was a typical ileitis and colitis. In some cases the colitis was continuous with the ileitis, while in others it was patchy.

The diagnosis rests on careful roentgenographic studies both by barium sulfate meal and enema.

Treatment is by colostomy and removal of the diseased ileum and sometimes the involved colon, followed by ileotransverse colostomy or ileosigmoidostomy.

EQUEN, MURDOCK.

"Esophageal Obstruction: Diagnosis and Treatment." South. Med. Journ., 28:1103-1107, Dec. 1935.

Esophogeal obstruction may be due to extrinsic or intrinsic causes. Extrinsic causes include retropharyngeal and peritonsillar abscesses, direct infiltration by carcinoma of thyroid, larynx or other neighboring structures, retrotracheal or substernal adenoma of the thyroid, tumor of the mediastinum, and aneurysm of the arch or other anomalies of the aorta.

The most common intrinsic cause is benign cicatricial stenosis resulting from the swallowing of caustics. Frequently, there is more than one stricture. The best treatment is immediate gastrostomy followed after the inflammatory process has subsided by retrograde dilatation. While foreign bodies rarely are causative factors, the history of swallowing one should always be seriously considered when obtained. Another cause of obstruction is cancer. Although it may be easily diagnosed, and is of slow growth and late metastasis, it is invariably fatal because of late diagnosis. Diverticulum is another cause not recognized as early as it should be. Suggestive early symptoms are a sense of irritation or of foreign material in the throat and an increase in mucus. Just after the patient takes a drink of water, sudden pressure over the diverticulum forces the water back into the mouth with the production of a gurgling noise. The most common diagnostic symptom of cardiospasm is the regurgitation of food which has not been acidified, although the patient usually believes he is vomiting. Peptic ulcer of the esophagus should be suggested by pain in swallowing. Congenital anomalies include the opening of the esophagus into the posterior wall of the trachea and a persistent shortening of an otherwise normal esophagus.

Any person who complains of difficulty in swallowing should have a careful history, physical, X-ray, and serological examination. If the diagnosis is not then established, esophagoscopic examination with biopsy where indicated, should be done.

The hope is expressed that every hospital will be equipped with specialists and instruments necessary for bronchoscopic or esophagoscopic examinations, as they now are for cystoscopic work.

GAY, L. P.

"Gastro-Intestinal Allergy: The Duodenal Ulcer Syndrome." South. Med. Journ., 28:1153-1156, Dec. 1935.

Some cases presenting typical duodenal ulcer symptoms can not have the presence of the ulcer confirmed by the usual clinical methods or operation. Other cases, where the ulcer is demonstrable, resist the usual medical or surgical treatment. The interesting suggestion is made that the cause in at least some of these cases may be a gastrointestinal food allergy. A series of 33 cases presenting allergic symptoms is given. In this group good clinical results, evidenced by relief from sensation of pressure, hunger, pain, and hemorrhage, were obtained in 70 per cent of the patients following the proper restriction of diet. Instances are noted where the symptoms could be repro-

X-RAY TIP WEIGHTED DUODENAL TUBE

Note the nine eyes, which extend for 10" so that when tube is in duodenum, drainage from the stomach and duodenum can be obtained at the same time, also that the end for 3½" is processed to appear opaque in X-ray or fluoroscopic examinations, and that the tip is weighted, thus the tube is easily carried into the duodenum. French Scale sizes 14 and 16 only. Each in box.

CLAY-ADAMS CO. WHOLESALE DISTRIBUTORS 25 EAST 26TH ST., NEW YORK

duced by the inclusion of the offending foods in the diet.

All duodenal ulcer patients are quizzed as to major and minor allergies of their antecedents and progeny as well as of themselves. Those presenting some type of allergic history are subjected to cutaneous tests which are read 24 hours as well as 20 minutes after injection. Because of the inadequacy of these findings, a trial diet and carefully kept food diary are also essential to the diagnosis. Fortunately, it is unusual to find more than 3 or 4 foods that actually reproduce the clinical symptoms. Wheat was the most common offender, and interestingly enough was closely followed in order by milk, potatoes, and rice, usually employed in the conventional ulcer diet.

The possible etiological significance of allergy in relation to duodenal ulcers may be supported by the following hypotheses: first, the mere muscular action of digestion may rub protein to which the patient is sensitive into the gastric or duodenal mucosa causing localized anaphylaxis and ulcer formation, secondly, the usual hyperirritability of the average allergic predisposes to pyloroplasm and gastric retention both of which are apparent contributing causes to ulcer formation and persistence, thirdly, the cyclic seasonal variation in ulcer symptoms may be due to the seasonal variation of foods ingested, and lastly, the pain of ulcers may be explained by localized anaphylactic spasm since focal reactions have been observed following the intradermal injection of test solutions.

The suggestions advanced seem worthy of very thoughtful consideration.

SCHMEISSER, HARRY C.

"Phytobezoar Diospyri Virginianae—Report of Two Cases." South. Med. Journ., 28:987-990, Nov., 1935.

Foreign bodies found in the stomach and intestines are of two kins: the preformed such as nails, hairpins, etc., and those formed after such substances as hair, food, etc. are swallowed. The general name "bezoar" is applied to this latter group. Bezoars may be subdivided into four groups: the trichobezoar or hair ball, the phytobezoar or food ball, the trichophytobezoar composed of hair and food (really a form of trichobezoar), and the shellac-bezoar which results when an alcoholic solution of shellac is precipitated in the stomach.

The two cases reported belong to the phytobezoar class since each was the result of the ingestion of a large number of persimmons. Thirty other authentic cases had been previously reported in the American literature. The two cases are described in detail and X-ray photographs are included in the article. Each patient had eaten approximately a quart of persimmons, there had been

Every doctor knows this family

THEY visit him off and on. They're not actually sick, but never quite well. They lack the vitality they should have. Compared with others, their personalities seem colorless. His questioning frequently reveals common constipation, due in most cases to insufficient "bulk" in their meals.

Addition of "bulk" to the diet is often indicated. But tests have shown that, with some individuals, the "bulk" in fruits and vegetables is largely broken down in the alimentary tract. This does not happen with bran.

Kellogg's ALL-BRAN provides an abundance of mild "bulk." Also vitamin B and iron. It may be served as a cereal or made into appetizing muffins, breads, waffles, etc.

This wholesome product is accepted by the American Medical Association Committee on Foods. Sold by all grocers. Made by Kellogg in Battle Creek, Mich.

The natural food that CORRECTS CONSTIPATION due to insufficient "bulk"

immediate nausea and discomfort or mild pain in the epigastrium, and within a very short time a mass appeared which was persistent. In one case the food ball was single and in the other multiple. Each case was treated surgically and followed by an uneventful convalesence after the removal of the mass through an opening in the stomach. Ulceration of the gastric mucosa was noted in one case.

FREEMAN, E. B.

"A Discussion of the Essential Procedures Employed in the Diagnosis of Diseases of the Esophagus." South. Med. Journ., 28:981-986, Nov. 1935.

Possibilities for the operative treatment of diseases of the esophagus have been increased by the recent advances in thoracic surgery. For this and other reasons more attention should be given to the diagnosis of those lesions. A consideration of the usual symptoms of dysphagia pain and regurgitation is not enough. In addition, roentgen ray examination, esophagoscopy and the passage of esophageal bougies are special procedures which should be utilized in most cases. The diseases may be considered under one of these groups: malignancy, chronic cardiospasm, cicatricial stenosis, diverticulum, foreign body obstruction, hysteria, and the rarer lesions such as polypus, peptic ulcer of the lower end of the esophagus, and congenital shortening of the esophagus.

In *malignancy*, the dysphagia comes on slowly, progressively becomes worse, involves at first only solid food and then later liquids. Regurgitation appears early and is quite troublesome but the quantity regurgitated is never large. Pain is a late symptom and seldom severe. X-ray examination shows an irregular, moth-eaten filling defect. Esophagoscopy not only affords visualization but may offer an opportunity for a biopsy. The passage of a carefully guided bougie will show a more narrow caliber obstruction than is seen in cardiospasm.

In *cardiospasm*, the dysphagia comes on suddenly in attacks between which there are long intervals of complete relief. Regurgitation appears early in the disease and the amount of food regurgitated becomes increasingly large. Severe pain is unusual but there is frequently fullness or pressure beneath the lower end of the sternum. Roentgen ray examination will show a large dilated esophagus smooth in contour and tapering to a point at the cardia. Esophagoscopy will confirm the possibility of a concurrent malignancy. The advantage of the use of a guided bougie has been mentioned.

The *dysphagia of cicatricial stenosis* is rather characteristic. The acute inflammatory reaction following swallowing of caustic fluids causes an immediate difficulty in swallowing. This subsides only to be followed later after cicatrization occurs, by dysphagia which may be quite serious. Regurgitation is not a prominent symptom. Neither is pain after the first irritation. X-rays show a definite obstructive area, with moderate dilatation above. Esophagoscopy is not of nearly so much importance. Bougies will aid in determining not only the extent but the number of strictures.

In *diverticulum* the dysphagia comes on slowly and is often accompanied by a swelling in the side of the neck. Regurgitation never occurs in the same degree as in chronic cardiospasm. Pain is neither severe nor characteristic. It is more likely to occur in the traction type and be referred to the mid-sternal or lower-sternal region. X-ray examination will demonstrate the pouch. Esophagoscopy is not of great value.

Foreign bodies cause immediate difficuly in swallowing and any attempt to do so causes pain. Otherwise the pain depends upon the amount of inflammatory change. Regurgitation is not a prominent symptom. Roentgen ray examination is of value not only in cases of opaque bodies but also in those of non-opaque bodies since the oral administration of an opaque mixture will contrast their shadow. Esophagoscopy is of great aid in treatment as well as in diagnosis.

The *dysphagia due to hysteria* depends upon the nervous state of the patient, rather than the character of food ingested.

Congenital shortening of the esophagus may cause quite severe pain. It is usually paroxysmal and may be accompanied by symptoms of mild collapse. Dysphagia may be present particularly if a large portion of the stomach is above the diaphragm.

Benign polyps and *ulcers* may be symptomless and the diagnosis depend entirely on esophagoscopy.

Esophagoscopy is emphasized as a procedure neither superfluous nor dangerous. It can be done in a well equipped office or out-patient clinic. Hospitalization is not necessary and the information obtained is frequently of great value.

J. Duffy Hancock, Louisville.

LOBEY, F. H. AND SWINTON, N. W.

"Gastrojejunal Ulcer and Gastrojejunocolic Fistula. S. G. O., Vol. 61; No. 5, Nov. 1935, pp. 599-612.

In a review of the literature the authors found a great range in the reported incidence of gastrojejunal ulcer following gastro-enterostomy (from 1.7 per cent to 24 per cent). Following gastric resection the reported incidence varied from 0.4 per cent to 10 per cent. It is generally believed that the true incidence of gastrojejunal ulcer and gastrojejuno-colic fistula is higher than is reported. Males are more frequently affected than females.

The ulcer is usually found either in the stoma of the anastomosis or in the posterior wall of the jejunum opposite the stoma. Numerous theories have been proposed to explain the development of these ulcers. The theory of the ulcer diathesis doubtless explains the recurrence of ulcer in certain types. Infection in one situation or another (teeth, tonsils, appendix and gall bladder) has been shown to be an important factor in the development of ulcer. In a series of 36 cases Hurst found only two who did not have tooth infection. Unquestionably hyperacidity plays a prominent role in the etiology of gastrojejunal ulcer. Various authors report hyperacidity in from 75 to 95 per cent of their cases of gastrojejunal ulcer. It does not appear that the use of non-absorbable suture materials, or the use of clamps, or high placement of the anastomosis are factors of importance in the development of these ulcers. Willis states that the "silk or linen suture is simply a bystander and not the cause of the lesion".

Certain features of the symptoms of gastrojejunal ulcer are characteristic. After a period immediately after operation during which the individual is entirely free from symptoms, there is a recurrence of ulcer symptoms of greater intensity. The pain is less regularly associated with meals and is much less responsive to treatment. Hemorrhage and melena, in the opinion of the authors, is much more common. The point of tenderness in the abdomen is more toward the left and above the umbilicus. The diagnosis is established by X-ray examination.

There is probably no effective prophylaxis against the development of gastrojejunal ulcer. The patient must understand that careful regulation of his habits as regards eating, drinking and smoking must be maintained perhaps more rigidly after operation than before. It is generally believed now that exclusion of the alkaline duodenal contents from the stomach, (as by closure of the pylorus during gastroenterostomy) predisposes to the development of gastrojejunal ulcer. Theoretically anterior gastroenterostomy should be complicated by a greater number of gastrojejunal ulcer than posterior gastroenterostomy because the site of anastomosis is farther from the duodenum, and therefore less resistant to the acid gastric contents. The senior author feels that anterior gastroenterostomy is preferable because such an anastomosis is farther removed from the transverse colon and for that reason is less apt to be the site of gastrojejuno-colic fistula. The technical difficulties of the surgical treatment of gastrojejuno-colic fistula associated with posterior gastroenterostomy justify that feeling. This complication is said to occur in about 11 per cent of the cases. The presence of gastrojejuno-colic fistula should be sus-

Detroit - J. D. 4-36 - Michigan

pected when a patient with gastrojejunal ulcer shows lienteric diarrhoea and loses weight even though their food intake is adequate. The diagnosis of large fistulas can be readily made by X-ray examination.

There is a distinct conviction on the part of most persons dealing with ulcer that patients with gastrojejunal ulcers seldom respond satisfactorily and permanently to medical treatment, but that in all cases medical treatment should be carried out to reduce the acidity and possibly also the area of inflammation reaction about the ulcer, thereby improving the patient's condition as an operative risk.

The surgical treatment of gastrojejunal ulcer may be simply unhooking the gastroenterostomy and re-establishment of the continuity of the intestinal tract (which is followed by a high percentage of recurrences of the primary ulcer), or it may be radical subtotal gastrectomy which is followed by a mortality disturbing to the patient and surgeon.

Small gastrojejuno-colic fistulas may be handled satisfactorily. Large fistulas present almost insurmountable problems. Block resection of the inflammatory mass and anastomosis of the free ends of bowel is a procedure of such magnitude as but very few patients can withstand. Resection of the stomach proximal to the site of the ulcer and re-anastomosis with the jejunum lower down (a sort of exclusion operation) has been performed successfully by the authors on two occasions.

Seven figures and a large bibliography accompany the article.

Nelson M. Percy, Chicago.

EXPERIMENTAL PHYSIOLOGY

BEST, RUSSEL R., AND HICKEN, N. FREDERICK.
Biliary Dyssynergia: Physiological Obstruction of the Common Bile Duct. S. G. O., Vol. 61, No. 6, Dec. 1935.

Dilatation of the bile ducts and intrahepatic biliary radicals indicates an obstruction to the free flow of bile from the liver to the duodenum. Calculi, inflammatory reactions, strictures, neoplasms, kinks, and functional derangements of the choledocho-duodenal-sphincteric mechanism are the most important obstructive agents. Considerable attention has always been placed on the organic obstructions of the common duct, but little attention has been paid to the physiological dysfunctions of the choledochal sphincter which are capable of producing an enormous dilitation of the entire bilinry tract.

The authors present case reports and experimental investigations which indicate that a hypertonicity or "dyssynergia" of the choledochal sphincter may mechanically interfere with the evacuation of the gall bladder and bile ducts,

TRI-CALSATE

The "Buffered"
Neutral Antacid

Non-Toxic
Non-Irritating

TRI-CALSATE is a powerful neutralizer of gastric HCL . . . yet does not stimulate gastric secretion or alkalize the stomach contents. The buffering effect of its end salts protects against a harmful alkalosis.

•

As no carbon dioxide is evolved during the reaction in the stomach, the distress from gastric distention and belching is eliminated.

•

TRI-CALSATE is non-toxic and non-irritating. The probability of gastro-intestinal irritation is remote . . . the kidneys are unharmed. Patients like it because it is palatable and easy to take.

•

Try TRI-CALSATE. It is available on prescription at your pharmacy or direct in 4 oz. and 18 oz. bottles.

•

Note: The quantity in the large size bottle has recently been increased from 16 to 18 oz. at no increase in price, making in effect a 12½% reduction in price to the patient.

Avoid the Vicious Circle of Alkali Neutralization

Write for literature and a trial supply of TRI-CALSATE.

thus producing a stasis of bile with a dilitation of the biliary radicals. Such a sphincterismus was demonstrated in four patients by direct roentgenographic visualization of the bile ducts following the introduction of lipoiodine. In one instance spastic contraction of the common duct sphincter persisted for three hours before it relaxed and permitted the lipoiodine to enter the duodenum.

Cases are presented showing that the hypertonicity of the common duct sphincter may be independent of, or associated with, a generralized infection of the biliary tract, the presence of stones, strictures, kinks or pancreatitis. The extirpation of the gall bladder, the removal of the stones, the division of the stricture and the drainage of the infected bile ducts do not always overcome the spasticity of the sphincter, for in some cases it persisted after these operative measures.

In many of these cases possessing a spastic dysfunction of the choledochal sphincter, a cholecystectomy would not necessarily be curative, for following the removal of the gall bladder, the intrinsic spasm of the common bile duct sphincter may continue. Four patients having a spasticity of this sphincter were studied by the authors by lipoiodine visualization for as long as 33 days following a cholecystectomy and the sphincterismus still persisted. This often accounts for the "hepatic neuralgia" and persistence of gall bladder distress following surgery.

Relief of these persistent symptoms depends on obtaining a relaxation of the spastic sphincter. Westphal has demonstrated that it is innervated by the autonomic nervous system and hence the hypertonicity can be relieved by atrophine. Intraduodenal instillations of magnesium sulphate or olive oil have also been used with beneficial results in these cases.

Charles T. Sturgeon, Los Angeles.

UNGAR, G.; CONTIADES, X. J., AND PALMER, R. G.

Libération de Substances Histaminiques par Excitation du bout Péripherique du nerf Splanchnique. C. rend. Soc. Biol., Paris, 120, 328-330. 1935.

Stimulation of the left splanchnic nerve of dog A produced an increased secretion of gastric juice from dog B (to which dog A had been anastomosed by the jugular veins and carotid arteries). This secretion from dog B occurred about eight minutes after the splanchnic nerves of dog A were stimulated. After several hours of such stimulation dog A showed haemorrhagic intestinal lesions. Injection of histamine into the artery supplying an isolated intestinal loop produced, after several hours, haemorrhagic lesions of the intestine similar to those produced by splanchnic nerve stimulation. Therefore the authors conclude that a histamine-like substance is liberated at the terminal nerve-endings of the splanchnic nerve.

M. H. F. Friedman, Montreal.

PASTEUR, VALLERY-RADOT.

"Urticaria." (A special number entirely devoted to the question in the review: "Nutrition", Paris, Tome 5, No. 1, 1935).

This is an almost complete review of our actual conceptions on allergy, following the works of Widal, Abrami, Joltrain and the author, whose authority is well known.

Urticaria is composed of a humoral trouble with vascular and haematologic perturbations in an individual already sensitized to an heterogeneous albumin. American and German Schools, in their research on skin reactions produced by an antigen, have confirmed the allergic nature of urticaria. Later, the authors have noticed that the crisis was launched not only by heterogeneous albumin, but also by a cristalloid or a physical agent, such as cold, in non-sensitized persons, although taking part in the colloidoclasic diathesis.

The Author *actually* recognizes four principal groups or classes of urticaria: 1. The *urticaria of anaphylactic* origin, as shown by skin tests; 2. The *urticaria or colloidoclasic origin* with no obvious urticaria; 3. *Urticaria due to various humoral troubles of sympathetic origin*, subsequent to an acido-basic imbalance of the serum by glandular insufficiency or by chemical deficiency of the digestive tract; 4. *Urticaria following an exaggeration of the normal vaso-motor phenomenon* in cases of vago-sympathetic dystonies, so that urticaria is not due to a univocal pathogenesis, the splanchnic system being liable to receive a stimulation from various humoral causes.

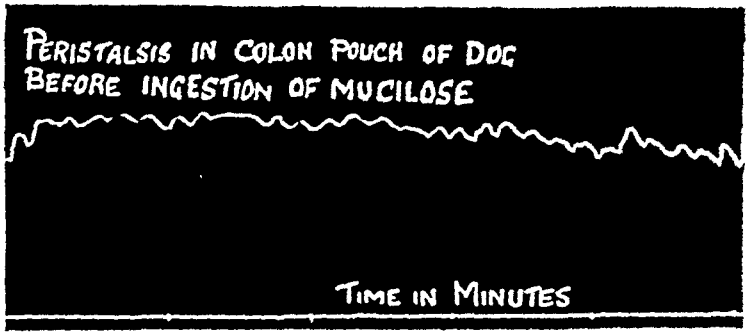
Each of these types is studied at length.

1. Urticaria due to an imbalance of the vago-sympathetic system. This urticaria is produced without anaphylaxis and is oftener met amongst females. It is revealed by the following symptoms: headache, Quincke's oedema, anguish, palpitations, fatique, emotivity, cryesthesia, erythematous patches on the skin, instability of the central temperature and of the pulse, arterial hypotension, sometimes thyrotoxicosis, increase in the basal metabolism, ovarian dysfunction. In these patients, the least incident will launch urticaria: emotion, meals, heat, cold, etc.

The treatment consists of an appropriate diet, intramuscular injections of a calcium soluble salt, repeated small doses of gardenal, belladonna, scopolamine, eserin, pilocarpin. The functions of the thyroid gland must be well investigated into as also those of the ovaries. These patients should be directed to take brisk walks or light efforts twice a day; hands should be ducked several times a day in cold water, if cold is the cause, and a tepid bath should be followed by a cold sponge bath. It is possible that these tests will show a reappearance of the phenomenon but after some time the crisis will decrease and disappear. One must admit this treatment is rather vague.

2. *Urticaria of digestive origin.* It is one which appears in an individual with a predisposition, following the ingestion of a special food without any previous digestive troubles. The rash is characterized by patches, some well circled, round or irregular, isolated or confluent, pink or red, localized or generalized, with dermographia in the neighboring territory, whereas edema is found on the mucosae, especially in the mouth. Pruritis precedes or follows eruption. Patches appear and disappear rapidly, but are identified by papules, vesicles or marked edema in the territories where the connective tissue is looser, such as the face, eyelids, lips. It lasts a few hours; the progress is rapid, but it may manifest in several attacks.

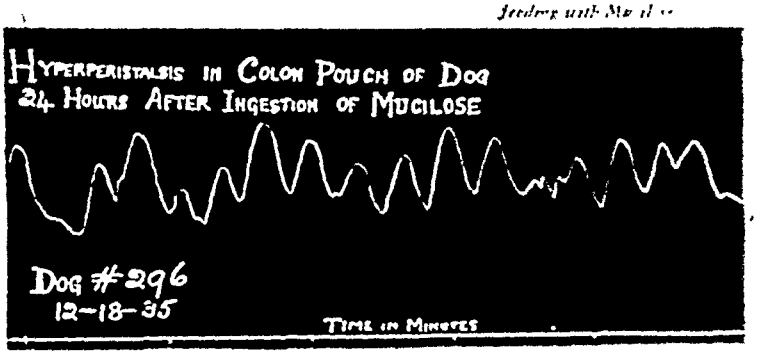
This state, sometimes accidental and unique, in other cases will show remittent or permanent. This eruption is accompanied by an acute gastro-intestinal state, often febrile, of the type of an acute gastritis with fever: coated tongue, nausea, vomiting, diarrhea, enteralgia, fever, sometimes preceding the eruption. These accidents will eventually occur in already dyspeptic individuals or long standing hepatic patients, etc.



This study of the gastro-intestinal urticaria is persued and divided into several stages:

1. *The alimentary phase*, caused by a determined food, the existence of which is proved in introducing intradermically a small quantity of it after sacrification.

2. *The digestive phase*, recognizable by an acute gastro-intestinal condition. At this stage, food is not always the direct cause, but may be the cause initiating the accidents following previous attacks. Pyorrhea is frequently held responsible for some of those conditions, and this opinion should be compared with the ancient one which explained the rash of the infants by the eruption of the first teeth. In such cases an *ad hoc* treatment aiming at the digestive condition should be reached: diet, digestive stimulants, intestinal desinfection, thermal cure.



3. *The hepatic phase.* The proteopexic and the proteolytic stage of the liver is apt to intervene in the mechanism of urticaria. Disturbances of the proteolytic function favor the formation of proteins which might produce urticaria and the troubles of the proteopexic function are liable to stop the

hepatic "barrier" opposed to the proteins absorbed from the bowels. The hemoclastic "shocks" due to an ingestion of milk well demonstrate this.

4. *The blood phase.* The essential phenomenon is produced in the blood: Arterial hypotension, leucopenia with inversion of leucocytosis, decrease in the number of the hematoblasts, the fall of the refractometric index, the blood hypercoagubility, are well in evidence. Shock is also tissular. This sudden sensitization of an individual to a food which he has ingested all his life with no accident suggests the idea of an idiosyncrasy but the process is the same.

5. *The skin or neuro-vegetative phase.* The vaso-motor trouble, *i.e.* eruption and pruritis, must be considered as symptoms of a nervous stimulation: one, the vaso-motor troubles, of neuro-vegetative origin, and the second, pruritis, due to a sensitization of the nerves, a consequence of the former.

One must bear in mind, in those cases, the *role* of the endocrine glands, but this neuro-vegetative sensitization will oftener result from a deficient condition of the digestive tract or of the liver.

In conclusion, in the presence of a case of urticaria, it is most important, according to the Author, that the condition of the digestive tract and of the liver be investigated: "and this must be accepted as a merely theorical conception, as experience shows that, in several cases, it is the only way of improving or curing a state of allergy".

THERAPEUTICS

HURST, ARTHUR F.

Ulcerative Colitis, Guy's Hospital Reports. Vol. 85, No. 3, pp. 317-355, July, 1935.

Hurst emphasizes the difficulty of distinguishing ulcerative colitis from bacillary dysentery by the use of the sigmoidoscope. Many instances in the past and present of finding *B. dysenteriae* in the stools and ulcer-bases of cases of ulcerative colitis are recorded, and Hurst frankly feels that *B. dysenteriae* as a group is the fundamental etiological factor in the disease.

Upon this may be built, from time to time, recurrences due to re-infection by other microorganisms,—*B. coli* and *enterococci* which have acquired enhanced virulence; parenteric organisms swallowed in the food; *streptococci* swallowed during acute tonsillitis.

Distinction from amoebic dysentery can usually best be made by the therapeutic test with emetine. Other confusing diseases are hemorrhagic proctitis, carcinoma of the pelvic colon and rectum, polypi, purpura, multiple telongiectasis, enteritis. "Regional" ulcerative colitis as, for example, of the sigmoid, may be recognized chiefly by the roentgen appearances.

The usually mentioned complications are dealt with at length. If achlorhydria be present, and lavage with hydrogen peroxide does not cause acid secre-

tion to re-appear, he then gives the patient HCl for the balance of his life.

Prospects of recovery appear good to the author provided patient and physician cooperate thoroughly and treatment be continued long enough.

The use of anti-dysenteric serum intravenously is the treatment which Hurst himself began 15 years ago, and from which best results are obtained. (Corroborative evidence of the efficacy of this form of therapy was presented in the August, 1935, issue of this Journal). This should be given as early in the disease as possible. Rest, a low-roughage diet, soothing enemas, codeine, belladonna, charcoal, iron, blood transfusions (when needed) are other phases of the medical methods which Hurst employs.

Caecostomy or appendicostomy frequently assists recovery in stubborn cases, but is reserved for those in which the whole colon is involved and in which improvement has failed to follow medical treatment. Colectomy and short-circuiting are usually to be condemned but occasionally, in spite of the hazards involved, a strikingly good result may be obtained. Dilatation of rectal strictures is safely accomplished by means of a finger-stall which is placed in situ and cautiously inflated with air until slight pain is produced. Hurst does not regard Bargen's organism as being the cause of the disease.

ABDOMINAL SURGERY

BUCKBINDER, J. R.

Surgical Limitations in the Treatment of Acute Suppurative Peritonitis. S. G. and O., Vol. LIX, No. 3, pp. 485-490, Sept., 1934.

The Author proposes to indicate what appear to be certain basic errors in the clinical appraisal and pathological diagnosis of acute peritonitis in the light of experimental and clinical observation, and to suggest what surgical limitations are imposed in the management of this disease. It has been shown that two functions of the peritoneum are of major importance; absorption and exudation. Absorption occurs in all parts of the peritoneum. It is retarded by albuminous solutions, by hypertonic solutions, by cold, by distension, by fibrin, and other substances. Exudation is the typical peritoneal response to inflammation. That exudation, which is normally serious, rapidly shows fibrin in the presence of irritation. Moderate inflammation provokes the formation of an abundance of fibrin, while a virulent infection may not produce any fibrin. It has been shown that no substance, however bland, can be introduced into the peritoneal cavity without causing the formation of fibrin. Steinberg concluded, from an experimental study, that the cause of death in diffuse peritonitis was the bacterial toxins; that intestinal paralysis, stasis, and bacteria play no part.

That there is frequently a basic error in the clinical diagnosis and the pathological diagnosis, especially in cases of acute spreading and acute diffuse peritonitis, is evident from a study of the clinical reports on cures of so-called "general" peritonitis. The clinical signs of spreading peritonitis will not usually tell its full extent; at operation one is not justified in determining the extent of the infection by exploring uninvolved portions of the abdomen. The lessened toxic reaction that accompanies fibrin immobilization, the usual absence of ileus, and a sharply demarcated zone of tenderness are differentiating features. Ileus, thready pulse, and vomiting are associated with a diffuse process. The Author considers the term "general peritonitis" a misnomer, and considers that in most instances it should be restricted to patients who are moribund.

In considering the problems involved in peritoneal drainage, the point that is frequently lost sight of is the difference in the reaction to drains of the diffuse

and localized types of infection. Drainage of diffuse peritonitis is always inadequate. Peritoneal abscess always requires drainage. Drainage can definitely be omitted when one is dealing with an unquestionably diffuse process. The Author believes that areas of definite encapsulation should be drained since they usually precede pus formation. Unencapsulated areas of pus are too often drained. A common example of such an error is the case of phlegmonous appendicitis in which unencapsulated pus has gone into the pelvis, or in which a spreading infection accompanies the appendicitis. It was for such a condition that surgeons a generation ago made multiple incisions, and put rubber tubes, or gauze, into each one. The Author has shown that drains in such cases are encapsulated within a remarkably short period of time, and subsequently do more harm than good. Experimentally the damage most uniformly evoked by such drainage is residual abscess, which abscess is less likely to disappear than such an abscess as forms in the absence of drains.

It would seem that the surgical treatment of spreading peritonitis is limited to the removal or closure of a septic focus, aspiration of the exudate, and closure of the peritoneum without drainage. The abdominal wound above the serosa must be drained. Both the experimental and clinical observations of the Author are opposed to the opinion that operation during a spreading peritonitis increases the rate of spread of the infection. Post-operative spreading peritonitis as indicated by distention of the abdomen, nausea, and vomiting, with mounting temperature and persistently high pulse should be treated by re-opening the abdomen rather than by waiting. Post-operative abscess should not be attacked until it is of sufficient size to assure both complete walling off, and indications of its location. In such instances the shortest route to the infection should be followed; fresh fibrin adhesions should be regarded as inviolate. A pelvic gravitation abscess impinging upon the rectum can be drained more readily through the rectum than along the old drainage tract.

WARREN, S., AND EBERHARD, T. P.

Mesenteric Venous Thrombosis. S. G. and O., Vol. 61, No. 1, pp. 102-121, July, 1935.

The authors review 73 cases of intestinal obstruction due to thrombosis of the mesenteric veins, and present two new cases.

In most cases no adequate cause for the thrombosis can be discovered. There are several predisposing factors the existence of which, along with symptoms of acute, or sub-acute, obscure abdominal distress, should suggest the diagnosis. Those causes may be grouped roughly into four major groups: Infections, hematogenous, traumatic and mechanical.

Pain which may be generalized or localized to one part of the abdomen is usually the presenting symptom. The character of the pain is not distinctive. Vomiting occurs early as a reflex phenomenon, and later as a result of obstruction. The vomitus may be bloody, like "coffee grounds" or fecal depending on the site of the thrombosis and its duration. Neither constipation nor diarrhea is characteristic of the condition. Some distention and a degree of shock soon develop. The pulse will be elevated, weak and frequently irregular. The temperature will be subnormal early. Marked leukocytosis averaging from 15,000 to 30,000 is one of the outstanding features of the disease.

All writers agree that melena is a diagnostic point in differentiating those obstructions with impairment of circulation and those without it. More general use of the diagnostic enema

THE
HYPERSENSITIVE COLON

When the enteric tract, especially the colon, has become sensitive to certain bacteria and their products, Karicin gives beneficial results. It detoxifies, adsorbs and inhibits the action of pathogenic organisms and their toxins, and thus aids in desensitizing the allergic condition of the intestinal canal.

Karicin is a ricinoleated emulsion of kaolin and mineral oil, prepared in such a way that the kaolin retains its adsorptive properties. Try Karicin on your next case of intestinal toxemia.

A tablespoonful mixed thoroughly in a half a glass of cold water is pleasant and effective.

TAXOL

SUGGESTION No. 3

Dear Doctor:

Carefully checked clinical and hospital records show that constipation is an ever present threat that must be seriously considered in all cases of gastric ulcer.

In a great many cases constipation is aggravated by the ulcer or may be the contributing cause, especially during the painful period.

Whether the cause is physiological or psychological we urge you to try Taxol as a valuable aid in the relief of this condition.

Taxol is a corrective. Its action is mild, soothing and effective. It has become a favorite prescription with hundreds of physicians not alone because its results are prompt and satisfactory, but also because when it is discontinued, or dosage lessened to one or two tablets a week, satisfactory bowel function is maintained without symptoms of distress.

May we send you samples of this really excellent preparation for the treatment of chronic constipation?

Very truly yours,

LOBICA LABORATORIES
1841 BROADWAY
NEW YORK

LOBICA LABORATORIES, 1841 Broadway, N. Y. C.
I would like a supply of TAXOL, also literature.

would increase the percentage of correct diagnoses in this condition.

If the disease is diagnosed early and surgical treatment instituted, there is hope of recovery. The prognosis is very poor if the condition is treated expectantly; after 24 hours of acute symptoms the prognosis is extremely bad. The consensus of opinion today seems to be that the infarcted bowel and its obstructed blood supply should be removed. It makes little difference whether anastomosis is undertaken at that time. Several authors have emphasized the importance of resecting the bowel far into healthy tissue. If anastomosis is to be undertaken at the time of the primary operation, it is all important to have healthy bowel for the procedure; any bowel with incipient thrombosis should be excised.

Eight tables and a large bibliography accompany the article.

ROLLER, C. S.

Mesenteric Cysts. S. G. and O., Vol. 60, No. 6, pp. 1128-1136, June, 1935.

Mesenteric cyst is possibly the rarest tumor in the abdomen. It occurs at all ages of life and along any mesentery. They seem to occur twice as often in females as in males.

It seems impossible to determine accurately the etiology of these cysts. The author presents a classification as follows: (1) Embryonic inclusion tumors, (2) chylous cysts, (3) bacterial or parasitic cysts, (4) traumatic cysts, (5) angiomata of blood or lymph vessels, and (6) gas cysts.

These tumors are usually symptomless but may give rise to symptoms of partial intestinal obstruction, or symptoms referable to whatever organ it may be pressing upon. Some authors have observed the tumors are more freely movable laterally than they are vertically.

The treatment of mesenteric cysts is purely surgical. Enucleation of the cyst without disturbing the bowel or its blood supply is the safest and most satisfactory method. Resection of the bowel and mesentery, or marsupialization of the cyst may be necessary.

The mortality varies from 10 to 50 per cent, but has been stated by Atchley to be 35 per cent for all cases.

The author reports 3 cases in detail.

Seven figures and a large bibliography accompany the article.

SEELY, H., AND ZOLLINGER, R.

Fundusectomy in the Treatment of Peptic Ulcer. An Experimental Study. S. G. and O., Vol. 61, No. 2, pp. 155-161, Aug., 1935.

The Authors performed experiments designed to determine whether fundusectomy performed in normal dogs of nondescript breed would permanently reduce the amount of free or total acid in the stomach. The fundus was excised from four dogs leaving a tube of stomach extending from the esophagus to a point within six centimeters of the pylorus. This tube was made up chiefly of the magenstrasse, was smooth and free of rugae. Postoperatively there was to be a marked drop in the amount of free and combined acid which, however, steadily rose until it reached the normal preoperative level after about eight months. At necropsy the stomachs were fixed in distended state and studied microscopically. Grossly they had the size and shape of a normal stomach, but contained no rugae. Microscopically they showed a rich distribution of acid bearing cells especially along the greater curvature.

From their studies the Authors conclude that fundusectomy has little to offer as a means of permanently reducing gastric acidity.

Nine figures, a brief review of the literature, and a bibliography accompany the article.

CANNED FOODS AND THE PUBLIC HEALTH

III. Chemical Preservatives

• Some of our readers have inquired as to whether or not chemical preservatives are used in commercially canned foods. In certain instances, this question was inspired by the fact that "canning compounds" were formerly sold for use in home canning and preserving operations. Such compounds, however, are rarely used by the housewife of today, and never by commercial canners.

We wish to state here that *no preservatives are used in commercially canned foods.*

Spoilage of food is principally caused by the growth and multiplication in food of microorganisms such as yeasts, molds, or certain types of bacteria. These microorganisms depend upon the food they inhabit for their nutrition and their life processes produce changes in the chemical or physical characteristics of food, or both. These changes lead us to state that the food has "spoiled".

Like other living organisms, these spoilage microorganisms can grow and multiply in a food only as long as conditions remain favorable for their existence. If any environmental factor, such as temperature, moisture or acidity, becomes unfavorable, these spoilage organisms are destroyed, or their development is inhibited.

All methods of food preservation have a common underlying principle; they all alter some factor or factors in the food environment so as to render conditions unfavorable for the growth or development of spoilage organisms in the food.

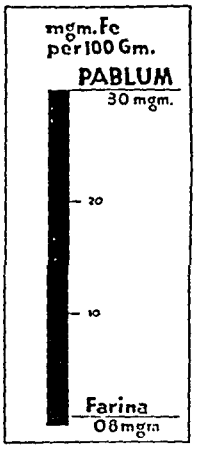
Thus, foods may be preserved by freezing or refrigeration, which serves to lower the temperature below that optimum for growth of certain spoilage organisms; dried foods keep because the moisture content has been reduced to an unfavorable low level; certain fermented foods keep because of the development of high acidity. All of these methods produce changes in the environment in which the food spoilage organisms must live.

Commercial canning is a method of food preservation in which the temperature factor in the environment is raised to a level above that optimum for growth of spoilage microorganisms. Thus, canned foods keep because in their preparation they are subjected to heat processes in hermetically sealed containers. The thermal processes raise the temperature of the foods to those temperatures at which the most resistant spoilage organisms present cannot grow or survive. (1)

The hermetic seal insures protection against future infection of the food by such organisms.

Thus, commercial canning is a method of food preservation which has for its basis the thermal destruction of spoilage organisms; no chemical preservatives are needed to insure preservation of the foods, and, consequently, none are used

AMERICAN CAN COMPANY



230 Park Avenue, New York City

This is the eleventh in a series of monthly articles, which will summarize, for your convenience, the conclusions about canned foods which authorities in nutritional research have reached. We want to make this series valuable to you, and so we ask your help. Will you tell us on a post card addressed to the American Can Company, New York, N. Y., what phases of canned foods knowledge are of greatest interest to you? Your suggestions will determine the subject matter of future articles.

For bland diet therapy, especially ULCER cases—PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastro-intestinal disorders is a deficient diet. An analysis made by Troutt of ulcer diets used by 6 leading hospitals in different sections of the country showed them to be "well below the Sherman standard of 15 milligrams" in iron and low in the water-soluble vitamins.[1] "Vitamin B would appear to be represented at a maintenance level in most cases," writes Troutt, "but the possible relation of vitamin B to gastro-intestinal function and appetite should make one pause before accepting a low standard."

Although Pablum has a low fiber content it is 37 times richer than farina in iron and in calcium, 4 times richer in phosphorus, and 4½ times richer in copper.

Low in Fiber—High in Iron

Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastro-intestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than farina and is an excellent source (+ + +) of vitamins B and G, in which farina is deficient. Supplying 8½ mgms. iron per ounce, Pablum is 8 times richer than spinach in iron.

Rich in Vitamin B

The high vitamin B content of Pablum assumes new importance in light of recent laboratory studies showing that avitaminosis B predisposes to certain gastro-intestinal disorders. Apropos of this, Cowgill says, "Gastric ulcer is another disorder which can conceivably be related to vitamin B deficiency. Insofar as the treatment of this condition usually involves a *marked restriction* of diet the occurrence of at least a moderate shortage of this vitamin is by no means unlikely."[2]

Requiring no further cooking, Pablum is especially valuable during the healing stage of ulcer when the patient is back at work but still requires frequent meals. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Pablum has the added advantage that it can be prepared in many varied ways—in muffins, mush, puddings, junket, etc. Further, Pablum is so thoroughly cooked that its cereal-starch has been shown to be more quickly digested than that of farina, oatmeal, cornmeal, or whole wheat cooked four hours in a double boiler (studies in vitro by Ross and Burrill[3]). In addition to the above advantages, Pablum is the only base-forming cereal (except Mead's Cereal which is the uncooked form of Pablum).

Pablum (Mead's Cereal thoroughly cooked) consists of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa, yeast, beef bone, iron salt and sodium chloride. [1-3] Bibliography on request.

Gastroscopic Observation Concerned with the Gross Anatomy of the Stomach: The Musculus Sphincter Antri; Observation of the Position of the Stomach; The Mucosal Folds

By

RUDOLF SCHINDLER, M.D.*

CHICAGO, ILLINOIS

THE aim of this paper is to describe the interior of the stomach as seen through the gastroscope and to contrast our concept of the gross anatomy derived in this way with the older views of gastric anatomy based on anatomic or roentgenologic methods. The findings are based on over 2400 gastroscopies.

It should be remembered that gastroscopy (18) is carried out with the patient lying on his *left* side. In looking through the ocular of a gastroscope one sees a round picture which may be subdivided in left, right, upper and lower quadrants. The "left quadrant" of the visual field is *not* the left side of the stomach. For this reason the orientation is very difficult. When the expressions: "left or right, "upper or lower" are used in this paper without any supplement they refer to the quadrants of the image seen through the gastroscope and not to the stomach itself.

We shall discuss the subjects to be considered under the following three headings:

(1) Interior parts of the stomach
(2) Position of the stomach
(3) Relief of the mucosa (folds rugae).

(1) *Interior Parts of the Stomach; the musculus sphincter antri.*

The subdivision of the cavity of the stomach into a *pars digestoria* and a *pars egestoria* is generally accepted. Cunningham (5) writes: "The *incisura angularis* and the *sulcus intermedius* are distinct." He found also this subdivision in the stomach of apes. The same findings have been described in the Sirenia. Most authors agree that the descending part of the stomach to the *incisura angularis* of the roentgenologists is the digestive part; the ascending part from the *incisura angularis* to the pylorus is the *pars egestoria.*

Nevertheless, there is much confusion in the nomenclature among the anatomists and among the roentgenologists as well. The gastroscopists do not like the word *"incisura"* because seen from the inside of the stomach there is no *incisura*, but a prominence, a kind of fold, which we are accustomed to call the *"angulus"* or angle. If this point be observed from within the cavity of the body (either through the gastroscope or in a dissected stomach of the cadaver or in a phantom showing the typical angle) it may be seen that this turning of the stomach from the downward to an upward direction produces a *parabolic curve.* This curve does not interrupt the anatomical continuity of the mucosal pattern.

It seemed necessary to Plenck (14) to give a name to that part of the greater curvature which is opposite to the angle. He called it "knee of the stomach." This name, however, is not important because the "knee" is neither of anatomical nor physiological importance.

While all authors agree, that on the lesser curvature the *pars egestoria* begins at the angle, a similar demarcation has not been found on the greater curvature. The pyloric glands extend along the lesser curvature to about the angle; on the greater curvature it has not been possible to find such a sharp limitation; but in any case they do *not* extend to the "knee" (Plenck (14)).

Anatomists found various circular contractions of the pyloric part of the stomach. His (9), for instance, found a marked *incisura* between the body and the *pars pylorica;* this latter was subdivided by muscular contractions in three parts *(camera princeps, camera minor* and *camera tertia).* Early it was shown that these contractions were inconstant and were the result of peristaltic waves developing at the moment of death.

In 1907 Groedel (7) believed he had found by X-ray a *sphincter antri pylori.* This is that part of the antrum from which peristaltic waves ran toward the pylorus.

The extensive literature will be found in Franz W. Mueller's paper (13) and in Plenck's (14) monograph. The conditions as revealed by gastroscopy are not even found by the X-ray-relief method. The work and concept of Cole (4), will be discussed later. It is surprising that in the standard work of Plenck the gastroscopic conceptions have not been mentioned.

If we look through the gastroscope toward the pyloric region, using as little air as possible for the inflation, we regularly find a prominent fold, which is sometimes so high that it hinders the view of the distal parts, and which is sometimes flat. Generally it appears as a twisted rope, cordlike. It usually begins exactly at the end of the parabolic line of the angle and runs over the greater curvature and the anterior wall of the ascending branch of the stomach.

*Visiting Professor of Medicine, University of Chicago.
Submitted January 7, 1936.

In the posterior wall it can either be missed or only poorly observed. The cordlike appearance may be absent, in which case the fold is smooth and of the same orange-red color as the other portions of the stomach. We have often photographed this fold through the gastroscope (17) and published several colored pictures (15). In rare cases the cordlike fold is observed above the angle and may then run over the lesser curvature. Such a case has been photographed by Henning (8). I should like to emphasize that ordinarily the smooth continuation of the lesser curvature is not interrupted by a prominent fold. However, we have seen the situation in a few cases in which the clinical picture gave the impression of abnormal spasms. It may rarely occur that this fold is beyond the angle and thus lies completely in the ascending part of the stomach. The gastroscopists call this fold the *musculus sphincter antri,* and it is evident that it constitutes the true division between the two parts of the stomach. Because it never runs over the "knee" of the stomach, but much more distal to it, it is possible that the pyloric glands extend along the greater curvature to this *musculus sphincter antri.*

What is (a) the physiological significance, and (b) the anatomical substrate of this *musculus sphincter antri?*

(a) In regard to its physiology it should be pointed out that, gastroscopically, peristaltic waves are observed only (with very rare exceptions in one of five hundred examinations) in that part of the stomach which is *distal* to this fold. This part is more of a globular cavity than a tube-like canal, and for this reason we call it the "antrum pylori." The peristaltic waves never begin at the *musculus sphincter antri* except in certain pathological cases. These waves of the antrum always begin at a place distal to the *m. sphincter antri.* They are seen as circular elevations, which move to the pylorus and are accompanied by a shortening of the antrum until the closure of the pylorus is complete. This is often accompanied by the formation of radial folds which give the pylorus a stellar picture. The point of origin of these peristaltic waves varies even in the same person if one observes long enough. Generally one has to wait about one miunte until the appearance of the first contraction which is often situated near the pylorus. The succeeding contractions become more energetic and originate more proximally, but never (this should be repeated) at the *m. sphincter antri* itself. I think we have to assume that the roentgenologists have considered as their *m. sphincter antri* the place where peristaltic waves begin. It may be that the true physiological function of the *m. sphincter antri* is to act as an obstruction or valve thereby preventing the food from entering the *pars egestoria* too early.

(b) What is this fold anatomically? How is it possible to explain the cordlike aspect? This latter question can be answered easily. It is evident that the mucosa is protruded as a high fold over which the normal mucosal folds run close together, not parallel to the greater curvature, but crossing at an angle. Korbsch contended that this oblique direction is only apparent and that it is effected by an oblique visualization through the gastroscope. This is not so. We often see perpendicularly into the antrum and yet the *m. sphincter antri* still appears cordlike. On the other hand we can sometimes observe these folds parallel to the greater curvature which, however, is infrequent. The high fold itself must be formed by some muscular action because it can be flattened out by insufflation of air, can reappear, and is generally not found in the stomach of the cadaver as a persistent fold of the mucosa.

Cole (4) published a drawing of the interior of the stomach showing a definite limiting fold between body and antrum, on both the lesser curvature and the greater curvature. This roentgenologic discovery has not been appreciated enough. This fold in Cole's drawing is formed only by mucosa and submucosa without participation of the *muscularis propria.* We cannot deny the correctness of this conception, but we have reason to think that the *m. sphincter antri* is formed by the *muscularis propria ventriculi* itself. This conception as well as all our observations about size, shape and situation of the *m. sphincter antri* corresponds exactly with the anatomical findings of Stieve (20) in 1919, who is the only anatomist to have described this region as I have seen it in about 2000 examinations with the gastroscope. He examined the stomach of four executed people immediately after death and found a thick compact circular contraction in the region of the *incisura angularis.* This contraction was so firm that the finger could not be introduced into the antrum. The peritoneum was smooth. The muscularis of the antrum was one to two mm. thick, while that of the body was 0.5 to 0.8 mm. In the contracted part the muscularis was elevated to form a circular wall, 6 mm. thick, which was protruded like a tile roof into the interior of the stomach. The wall of the stomach at this point was two cm. thick. This thickened circular muscle consisted only of contracted circular muscle fibres. After opening the stomachs the antrum and the body showed a smooth surface. Only in the region of the contraction, broad, comb-like and ridgelike folds were found. These were generally parallel to the greater curvature but some were oblique. This anatomical picture corresponds so well with the gastroscopic findings that we have reason to suppose that the *m. sphincter antri* in the living man is a constant formation caused by a contraction of circular fibres of the *muscularis propria* itself.

We believe that our numerous gastroscopic observations together with the anatomical description of Stieve and the roentgenological conception of Cole should settle the question of the subdivision of the stomach once and for all.

Gastroscopically, the *nomenclature* of the parts of the stomach must then be: cardia, pylorus, anterior wall, posterior wall, lesser and greater curvature and the cavities of the "body" *(corpus)* and of the "antrum." Both cavities are separated in the region of the "angulus" by the high fold of the *musculus sphincter antri,* which is generally developed only on the anterior wall, posterior wall and greater curvature, and not on the lesser curvature. It may be practical to add the name of "fornix" for that part of the body which in upright position lies above the cardia. This nomenclature has been used by us since 1923 and has been adopted by Moutier (12).

(2) *Observations on the position of the stomach.*

The position of the stomach is seen differently by the anatomists and by the roentgenologists. There is

probably no other organ of the body, about whose gross position the opinions differ so much. The reason is the extreme mobility of the stomach, the change of its position due to various influences and different conditions under which the two methods have to be used.

(a) *The mobility of the stomach.* We often find the statement, that the stomach has two fixed points, cardia and pylorus. Gastroscopy shows us that this is wrong. The cardia or at least the diaphragmatic portion of the esophagus is certainly fixed, but not the pylorus. The pylorus generally can be well seen through the gastroscope if the patient is lying on his left side or on his knees and elbows. Moving the right shoulder forward often brings a hidden pylorus into view when using the left side position. Since the end of the rigid gastroscope always lies at the left side of the vertebral column and posteriorly, and since the end of the flexible gastroscope never leaves the posterior wall of the stomach, the pylorus appears generally in the left upper part of the gastroscopic field. This fact proves that the pylorus has left its regular position at the right side of the spine and has fallen toward the anterior abdominal wall of the patient. The short end of the duodenum between its retroperitoneal part and the pylorus is long enough and moveable to allow this important shift of the pylorus. This movement can be so extensive that the pylorus appears exactly at the left side of the observer. We have seen this in persons in whom no adhesions could be suspected. That means that the pylorus has fallen so much forward toward the abdominal wall that it is seen at the *left* side of the spine and that the cardia and pylorus are lying in a *sagittal plane.* The stomach has reached its embryologic position. In these cases, the gastroscope runs over the greater curvature or at least very close to it; this event confuses the beginner completely; he cannot imagine such an enormous mobility of the pylorus. This fact that in some cases the pylorus is found at the left side of the spine in the left side position of the patient, has been proved anatomically by Bensaude, Gregoire, and Rachet (2).

(b) *The inclination of the posterior wall.* The course of the stomach between the cardia and the pylorus is most complicated and varied. The best anatomical description has been given by Franz W. Mueller (13). According to him, the position is altered by:

(1) sex (Schlesinger), (2) position and size of liver, (3) position of diaphragm, (4) position and fullness of the intestine, (5) exterior shape of the body, (6) condition of the abdominal wall, (7) position of the body.

(1) In my gastroscopic observations I could not find any difference between the sexes.

(2) The influence of the liver cannot be determined by means of gastroscopy.

(3) A decisive influence of the diaphragm is observed as continuous shifting of the gastroscopic picture in different directions corresponding to respiratory movements.

(4) In my textbook and atlas of gastroscopy of 1923 (15) I referred to the varying fullness of the intestine due to the fact that in the different gastroscopies made in the same patient the pylorus was easily seen at one examination, but could not be found at another, although the tonus of the muscular wall of the stomach had not changed.

(5) The exterior shape of the body plays the greatest rôle in determining the position of the stomach. This will be discussed later.

(6) I have not observed any influence of the abdominal wall upon the stomach as viewed through the gastroscope. I agree in this point with the X-ray findings of Moody, van Nuys, Chamberlain (11).

(7) It has been mentioned that the position of the body is of fundamental importance for the position of the stomach. Although the French school (Bensaude, Rachet) has studied this point, the influence of the left side position has been neglected.

A plane which joins lesser and greater curvature is a warped one. In the middle of this plane between the two curvatures is the *axis* of the stomach. The plane of the axis is bent by the direction, the inclination and the rotation of the stomach. These three influences cause the plane to be warped. The inclination and rotation are little known to the roentgenologists who generally see the stomach in the anterior-posterior direction. If they would become accustomed to examine the stomach, in any case, also from the left and from the right side, they would have quite another conception of the shape of this organ. The divergence between the roentgenologic and anatomic conceptions is easily explained by the fact that the roentgenologist rarely observes the stomach in this direction and that it is impossible for him to observe the stomach in the most important transverse plane. The anatomist finds that a vertical position of the axis of the stomach never occurs, because the region of the fornix is always separated by the left liver lobe from the anterior abdominal wall while the lower pole approaches the anterior wall and often joins it. We have seen that even the pylorus often approximates the anterior wall in certain positions. The general direction of the whole stomach runs from cranial-dorsal toward caudal-ventral. In a frontal plane which is routinely used in the X-ray examinations the stomach appears shortened.

The criticism of Fr. W. Mueller (13) about the X-ray method seems to be much too harsh. He points out that the axial plane is rotated so that the greater curvature is turned toward the anterior wall and the axial plane between the two curvatures approaches the transverse plane. For this reason, the lower border of the stomach as seen with X-ray is a line of the posterior wall and not the greater curvature. This is certainly true in a great number of cases, but it should be considered that the stomach *may be stretched* by the heavy barium and then may leave its transverse position, which is so unfavorable for an X-ray examination.

The question to what degree and how often the stomach can be stretched can be settled to a certain extent by gastroscopical researches. Gastroscopy never can determine the course of the axis with certainty but often it can determine the course of the posterior wall. We choose a patient, in which the introduction of the rigid gastroscope is extremely easy, and in which it can be pushed to the lowest depth of the stomach. If we lay this patient on his back and introduce a flexible, but not elastic, metal tube and then make an X-ray exposure from the left side, we see that the tube lies at the cardia at the side of the spine and that it bends forward toward the anterior wall in a curve whose angle scarcely surpasses 30°. This ex-

periment proves that even in the most favorable position in the most apt patient the posterior wall of the stomach does not continue in the same axis as the esophagus, but that it forms an angle of about 30°. The stomach axis proper has to lie still more anteriorly, but that is not so important for the practical purpose of gastroscopy.

How often is it possible to stretch this angle and cause the posterior wall to become a straight continuation of the axis of the esophagus? This can easily be decided by recording the experiences with the rigid gastroscope. In 45 to 50% of all cases it was not possible to introduce this instrument into the lower depth of the stomach. Generally it was stopped by the posterior wall two cm. beyond the cardia. It became evident that the type of constitution played the greatest *rôle*. The 50% in which the stretching of the stomach was impossible were markedly obese, heavy people with short neck, belonging to that type of constitution which now we are accustomed to call a "pyknic" constitution. On the other hand, the remaining 50% in which the complete introduction of the rigid instrument was possible, belonged to the "asthenic" constitution. There were exceptions in both types.

The use of the flexible gastroscope permits better judgment about the size of the angle which the posterior wall forms with the axis of the esophagus. The flexible gastroscope gives a round picture only when its curve does not exceed an angle of 34°. This gastroscope is not only flexible but also extremely elastic and by its elasticity it stretches the posterior wall like a rigid gastroscope (Moutier (12)). It can, however, be introduced to the lowest depths in all those cases in which a stretching of the stomach wall is impossible. We find that in about 5% of all persons examined the picture does not become completely round, indicating that the angle between the axis of the esophagus and of the direction of the posterior wall is greater than 34° even under the stretching influence of the elastic instrument. A curious phenomenon is still seen in 2% of the other cases. If the flexible gastroscope is introduced into the lower depth of the stomach, the picture is quite round because the long elastic part has strength enough to stretch the posterior wall to an angle of 34°. If the instrument is then withdrawn and its tip is but 5 cm. beyond the cardia, the picture suddenly becomes disc shaped. This short piece of the instrument is not strong enough to prevent the stomach wall from bending it to an angle greater than 34°.

(3) *The "Relief" of the Mucosa (Folds, Rugae).*

Gastroscopy demands an inflation of the stomach by the smallest amounts of air. With this the "relief" of the mucosa can be studied excellently. It is somewhat astonishing that the results do not correspond completely with the results of the X-ray relief method.

We have tried to demonstrate, by X-ray relief-examination, marked pathological changes repeatedly seen with the gastroscope. One case was that of a rigid fold running over the posterior wall from an artificial operative opening between stomach and intestine. This fold contained numerous small rigid nodules. Another case was a man whose stomach mucosa was shown to numerous physicians in gastroscopic courses. As an end result of a very severe hypertrophic gastritis, there were two sickle-shaped, firm folds of the greater curvature, crossing it perpendicularly. The smaller one was about 6 cm., the larger one about 8 cm. beyond the cardia. We did numerous fluoroscopies and took many films in order to demonstrate these folds roentgenologically. This was impossible. We have already discussed the fact that it is generally impossible to demonstrate the true *m. sphincter antri* roentgenologically.

On the other hand, we often see on X-ray relief-pictures formations which are not observed through the gastroscope. The antrum, for instance, is gastroscopically free of mucosal folds, yet they show regularly in the relief technique films. I cannot fully understand this difference. Because I see such folds only when the patient vomits or retches, I suggest that the contraction of the *muscularis propria* causes these folds.

I have never seen any activity of these folds. This corresponds with the findings of French authors (Duval, Roux, Béclère, Moutier (6)). They found "that the folds were constituted by a vasculo-connective-tissue axis covered by mucosa; the *muscularis propria* does not participate in their formation. It was also noted that the puckering is never caused by follicular hyperplasia or lymphoid proliferation. One simply noted, in certain cases, at the base of the folds, besides at their summit, a thickening of the *muscularis mucosae.*"

The gastroscopic observations have often been recorded by photography through the gastroscope (Henning (7, 8), Schindler (17)). Pictures by means of the "gastrophotor" are of questionable value because they are taken blindly, not knowing which way the apertures point (16).

The gastroscopic observations of the interior of the stomach are as follows: The cavity of the antrum does not show any folds as mentioned above. The peristaltic contractions run over the wall as circular protrusions. The folds of the posterior wall are much larger than those of the anterior wall. Apparently this fact is not only caused by the greater distance of the objective from the mucosa of the anterior wall, but it is, also, observed in the beginning of the examination when the anterior wall is very close to the objective. The folds of the posterior wall are not so regular as they are seen in the X-ray relief pictures. Gastroscopically the folds are generally longitudinal, joined by many cross folds and are "fork-like" (Henning). They are more numerous than the X-ray reveals. Often they are much distorted and form a network. This network is a very common finding in the anterior wall. Here the folds are much more delicate than on the posterior wall. In the greater curvature, the folds are more regular and parallel than in the other portions of the stomach. A prominent fold which separates the greater curvature from the anterior wall has been described by Henning, but I have not regularly seen this. Even in the greater curvature the folds are generally serpiginous. The upper lesser curvature which is seen on a tangent appears as an overhanging fold, but there is in reality no fold. On the contrary, the lesser curvature, in which the folds of the "magenstrasse" (Aschoff (1)) might be expected to be seen, is the smoothest part of the whole stomach. In special cases, some flat parallel folds are observed. The network of folds is very regularly *found*

in the fornix. The formation of the *m. sphincter antri* with its crossing folds has already been described.

On the whole, the normal mucosal folds as seen gastroscopically are much more delicate, more numerous, and more irregular than those seen in X-ray relief pictures.

SUMMARY

1. Gastroscopy gives important information with regard to the gross anatomy of the stomach and in many respects amplifies and alters the concepts gained through anatomic and roentgenologic research.

2. The interior of the stomach is separated into two distinct cavities: that of the body and that of the antrum by the marked *musculus sphincter antri.*

3. The *m. sphincter antri* is situated at the level of the "angulus" of the stomach, but is a separate entity from the "angulus." It has a cord-like appearance. It is probably formed by a circular contraction of the *muscularis propria* which is crossed by oblique folds of mucosa.

4. The paristaltic waves in the antrum do not begin at the *m. sphincter antri,* but at different points distal from it.

5. A nomenclature adapted to these facts is suggested.

6. The pylorus is mobile. In the left side position it falls toward the anterior abdominal wall. In some cases it may even reach the left side of the abdominal cavity, so that pylorus and cardia lie in a sagital plane.

7. The position of the stomach is chiefly influenced by the body build. The position of the body, fullness of the intestine, and the movements of the diaphragm also affect the position of the stomach.

8. The posterior wall of the stomach always forms an angle with the axis of the esophagus, so that the posterior wall runs toward the anterior abdominal wall. This angle may be stretched by mechanical means in about 50% of all cases. It is greater than 34° in about 7% of all cases.

9. The mucosal folds of the stomach are best observed by gastroscopy. They form a delicate, irregular network which is much more marked in the posterior wall than in the anterior wall, usually absent in the lesser curvature and always absent in the antrum. These delicate folds do not seem to correspond completely with the X-ray relief findings.

10. In this paper the gastroscopical findings are compared with anatomical and roentgenogical findings.

Relationship of Histologic and Gastroscopic Findings in the Diagnosis of Chronic Gastritis: A Brief Review

By

RUDOLF SCHINDLER, M.D.*
CHICAGO, ILLINOIS

THE Pathologists (Knud Faber (3), Konjetzny (11), Paschkis and Orator (16), etc., call the mucous membrane of a stomach normal only when no interstitial cell infiltration whatever is seen. The main experiments and sections have been made in newborn infants. Such a type of stomach, however, has been found also in older children and in adults. Paschkis and Orator found in an extensive number of autopsies only 10 stomachs which could be called "normal"; so that practically no adult had a normal stomach but everyone had a chronic gastritis. This conception does not correspond with our clinical conception of a disease (Katsch (10)). The fundamental problem of medicine: "what is a disease?" is profoundly affected by the above mentioned statements.

In my opinion an adult who does the hardest work, who enjoys life without any restriction, who never has any troubles from the stomach or of other organs, who in the immediate future does not develop such troubles from an already present but silent or incipient disease, cannot have a diseased stomach.

*Visiting Professor of Medicine, University of Chicago.
Submitted January 7, 1936.

In the skin, for instance, a scar is not a disease although it is not "normal"; the anthracosis of the lungs is not present in the newborn, but is not a disease in the adult (except some special cases); we have learned that the appendix may show some cellular infiltration even though its owner is healthy, so that we have not the right to extirpate such appendices.

If we should accept the above mentioned definition of the pathologists we should lose at the same time the clinical significance of the entity "gastritis" which has been established after such long efforts. On the other hand, we must admit that there are many stomachs which show such marked histological changes, especially tremendous interstitial infiltration that a pathologic process is evident. In these cases we never have to deal with healthy adults but with suffering patients.

In accordance with the conception of the pathologists, almost every adult should suffer either from subjective or objective symptoms. The coincidence of such symptoms with the well known "histo-pathologic changes" is naturally not conclusive of a causal connection. This is, however, too easily forgotten. Knud Faber, for instance, quotes Bennet and Ryle (1) who found among 100 apparently healthy students four cases of anacidity. He believes that such a fact is often regarded in England as decisive proof of the existance of an inborn constitutional anacidity. "But," he asks, "how do we know it is inborn? It may just as well be a state subsequent to an acute gastritis." This is evidently correct. As almost all adults show some histological state of "gastritis," one should expect even a much higher percentage of anacidity. Thus there is even more probability that the theory of the "constitutional" anacidity is correct. Nevertheless Knud Faber forgets a third factor which has been proved with the greatest exactitude, namely the influence of psychogenic stimuli upon the secretion of stomach juice (Pavlov (17, 18), Heyer (8), etc.)). It is astonishing that not more of these young adults show a lack of free hydrochloric acid because the introduction of a stomach tube is so often connected with feelings of disgust and apprehension. Although a chronic gastritis in these four cases perhaps was present it has not been proved.

Thus we see that the anatomical conception of today of chronic gastritis disagrees with the clinical conception. An agreement could be reached only if it would be possible to draw anatomically a sharp line between those adults who are suffering from their stomachs and those who are not. It is so extremely difficult because the material is not available. Healthy persons do not die and it is almost impossible to exclude the possibility that the stomach has been affected by other diseases present. We hope that biopsies may later settle these questions. It will, however, not be easy to obtain permission to carry out biopsies in many healthy people.

The other method which has demonstrated the frequency of chronic gastritis; *i.e.* gastroscopy, works under quite different conditions. They are partly more favorable, but gastroscopy also has its disadvantages. That it is a subjective method does not counteract its scientific value. We are certainly spoiled by the objective documents of the anatomists and of the roentgenologists. If the conscious subjective observation would be without value, Laennec's discoveries, the whole development of ophthalmology after the invention of the ophthalmoscope, the development of urology, proctology, etc., would have been impossible. The hope that photography would help has not been fulfilled. The author has proved this in several papers. In gastroscopy, however, the most careful observation does not protect against errors. It is significant that the author believes that he saw numerous gastric ulcers without any extensive gastritis, while Korbsch (13) believes he observed extensive gastritis in each case of ulcer. It is, furthermore, not only possible but very likely, that very slight changes are overlooked with the gastroscope, which, as is well known, pictures important parts of the stomach wall in reduced size.

On the other side, gastroscopy has decisive advantages: it enables one to study carefully, and repeatedly, stomachs of people who are capable of doing heavy work, enjoying their lives to the fullest extent. The author has made one series of such examinations in Europe. There were always some healthy young girls or old men ready to be gastroscoped for a few marks; they were often observed as a check in the establishing of the method and also, still later, in the numerous gastroscopic courses during which the students introduce the gastroscope in them. In this country this important method of examining normal people seems to be more difficult. A very good knowledge of the "normal" mucosa, as seen through the gastroscope, was established in this manner. The author believes that he knows exactly when some parts of the mucosa do not look like those of normal people. In contrast to the anatomic conception, he found that all those persons with abnormal appearances of the stomach mucous membrane were invariably suffering from stomach disorders or other diseases affecting the stomach (pernicious anemia, etc.). The changes seen through the gastroscope have been described elsewhere. If they were controlled microscopically (after operations) regularly very marked changes were found.

CONCLUSIONS

If we compare the two methods, histologic and gastroscopic, regarding their value for the establishment of the entity; "chronic gastritis," we find:

(1) The positive findings in histology do not prove the existence of a clinical "disease" of the stomach. Almost every adult shows some interstitial changes in the stomach mucosa as compared with the newborn. To say that ulcer, cancer, or blood diseases, etc., are the result of such histologic changes is permissible only when the changes are very marked.

(2) Gastroscopy allows repeated study of the interior of quite healthy individuals and the establishment of a morphologic endoscopy for the normal stomach. Changes of this picture prove, with greatest certainty, the presence of an organic lesion, especially of chronic gastritis. Minor pathologic changes are of the highest clinical and scientific significance.

(3) A method to harmonize anatomic and gastroscopic findings urgently is needed.

Intragastric Photography*

By

REUBEN FINKELSTEIN, M.D., F.A.C.P.

BROOKLYN, NEW YORK

THE visualization of the inner surface of the stomach as a clinical procedure has been the objective of all gastro-enterologists. This was partly realized when Mickulicz in 1881 reported the first successful use of the gastroscope. Since then, the instrument has been greatly improved first by Rosenheim, later by Elsner, Schindler, Einhorn and Chevalier Jackson. Nevertheless, the inherent danger of passing a rigid tube through the esophagus cannot be overcome.

About the beginning of the present century, roentgenography was introduced and soon almost entirely displaced gastroscopy. The roentgenogram, however, is merely a shadow picture of the organ studied. Abnormal changes may be observed readily because of its distinct outline. Yet, lesions of the anterior and posterior walls of the stomach and of the cardiac region are frequently missed because of the contained barium mixture which completely covers these areas. Also, shallow ulcers and small infiltrated areas on the lesser and the greater curvatures often are overlooked; in fact such lesions are very difficult to diagnose by either fluoroscopy or films. Mucosal "relief" studies more recently have been introduced which, in the main, have added little to our knowledge. Mechanical pressure exerted against the stomach walls is not a normal condition. Since only a small amount of barium mixture for "relief" films or the "compression" technique, is used, the stomach is practically in a collapsed state causing the mucosal folds to overlap, thus often concealing a small ulcer.

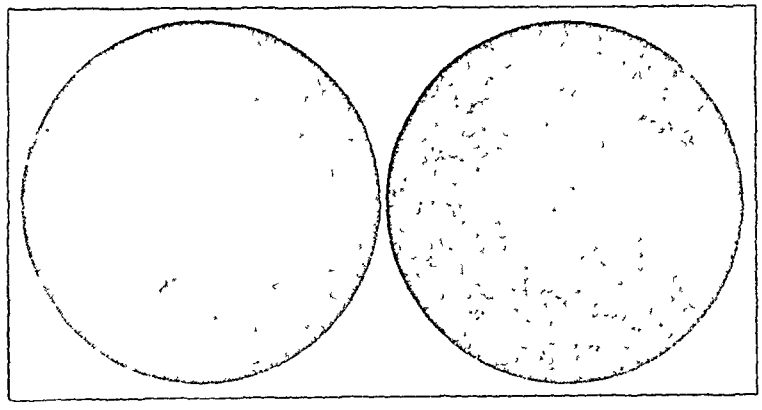

Fig. 1. Picture of normal gastric mucosa. Refracted spots due to contained mucus.

Within recent years attempts have been made to revive the use of the gastroscope. But even with the modern technique the entire procedure is time-con-

* From the Gastro-enterological Service of the Beth-El Hospital.
Submitted October 21, 1935.

suming and requires the skill of a highly trained expert. The best modern flexible instrument still presents numerous contraindications and its field of visualization is limited. A large portion of the lesser curvature and the posterior wall and almost all of the cardiac portion of the stomach are hardly ever seen. Another inherent defect in its use is that the instrument is not self-recording.

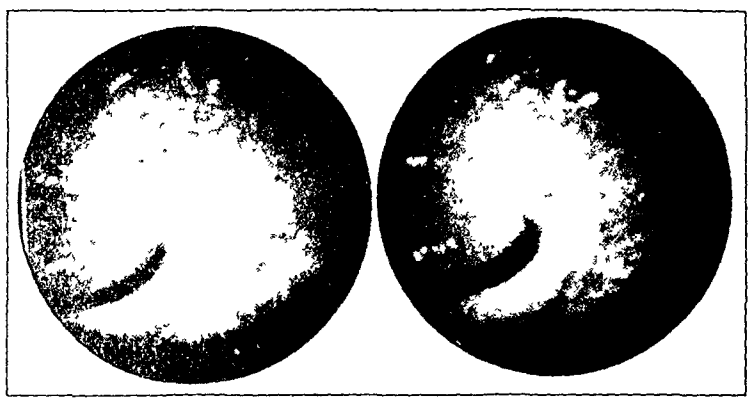

Fig. 2. Normal mucosa. Picture shows pyloric opening.

Intragastric photography with the camera in the stomach cavity would seem to offer a practical method by which the inner surface of the living stomach could be visualized. An instrument for this purpose was invented by Mr. Bach, with the clinical assistance of Professor Porges and Doctor Heilpern, at the Wenkenbach Clinic in Vienna. It was introduced into this country about six years ago. Since then, the gastro-intestinal department of the *Beth-El* Hospital has made constant use of this instrument. Our studies have included normal stomachs in patients who were admitted for conditions other than gastro-intestinal diseases, stomachs of patients in whom lesions were diagnosed by means of roentgenological examinations and stomachs of patients who gave symptoms of gastric lesions which could not be substantiated by roentgenography.

APPARATUS AND METHOD

The *instrument* for taking intragastric pictures consists essentially of a flexible stomach tube carrying at its distal end a tubular camera of about 30 French gauge, together with a small bulb for illumination so constructed that, when activated by current furnished by a special transformer, it yields an intense bluish white light of 20,000 candle power for 1/120 of a second. The camera carries eight films divided into two groups of four, each group photographs the entire circumference of the stomach at a different level. By means of two pin point holes placed before each film, pictures are obtained so that at one exposure eight stereoscopic photographs (sixteen pictures) are made. These eight films are marked so that one can readily tell which part of the circumference of the stomach is pictured on the film.

Intragastric photographs are best taken in the morning after the subject has fasted overnight. In our clinic the stomach is further emptied of its secretion by means of a Rehfuss tube; where there is pyloric stenosis with retention, the stomach is lavaged. The camera tube is then introduced in the same manner as an Ewald tube. In our experience, we have found that the use of the fluoroscope helps to localize the camera. The stomach is now inflated with air through a special opening in the tube, the shutter is opened and the films are exposed by flashing the lamp, the tube is then withdrawn. With our present technique, the whole procedure takes from twenty to thirty seconds. The camera is roentgen ray proof and the films are not fogged by the use of the fluoroscope.

The inflation of the stomach with air is necessary to give distance between the camera and the stomach wall, and also to smooth out the mucosal folds, thus rendering it possible to reveal hidden lesions. The air-inflated stomach has a tendency to approach more nearly the illustrations

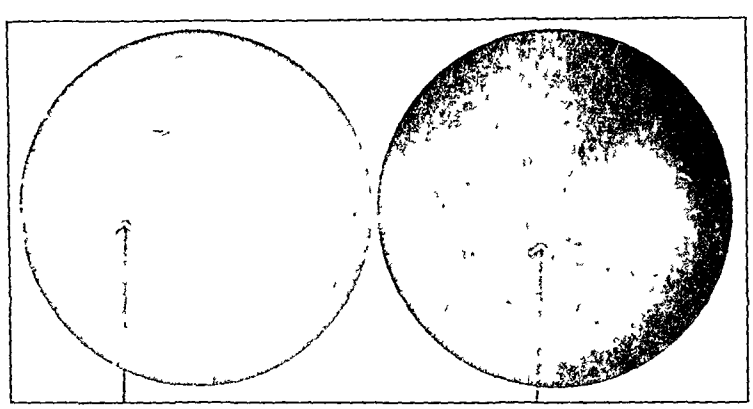

Fig. 3. Picture shows shallow gastric ulcer. X-ray was negative. History is pain with relation to food, also bloody vomiting.

of the stomach in the older anatomical text books. The fundus is higher, the greater curvature more to the left, and the pylorus somewhat lower. This is especially true in the orthotonic and hypotonic types of stomachs.

Intragastric photographs show the condition of the mucosal surface exactly as it appears. They reveal any defects which may be caused by erosions, ulcerations or growths, benign or malignant.

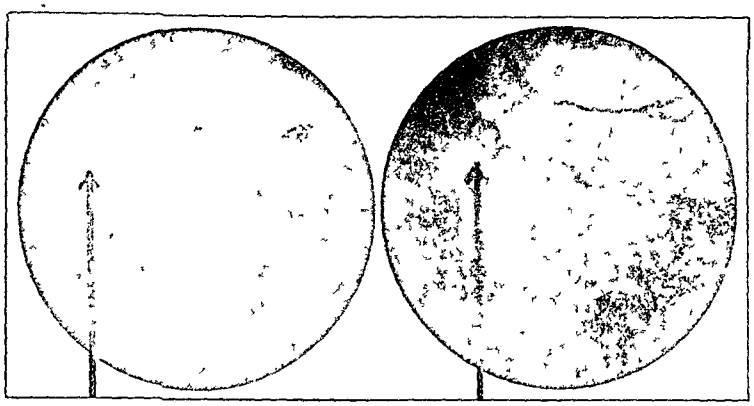

Fig. 4. Picture shows ulcer at pylorus X-ray diagnosis pyloric carcinoma. Patient improved under treatment. Hyperchlorhydria of gastric contents.

Skill in the interpretation of the resultant pictures may be acquired by studying the photographs obtained in normal and pathological stomachs and checking them against these specimens obtained by surgery or at autopsy.

The pictures taken in *normal stomachs* show normal sized rugae radiating along the axis of the stomach with some intertwining on the greater curvature. The pyloric canal is readily visualized In *chronic gastritis*, the rugae may be seen as markedly thickened ridges. The shallow *ulcer* is noted as a small crater with a ridge surrounding it, while the penetrating ulcer is shown as a deep crater with rugae drawn toward, or radiating from it *Tumors* appear as masses with regular or irregular outline.

AUTHOR'S STUDIES

In our first few attempts we had poor results but, as our technique improved, pictures became uniformly good. To date we have photographed the stomachs of 216 patients. All patients but two were roentgenographed either before or after the intragastric photographs had been made.

Roentgenography and intragastric photography agreed in the examination of 153 patients. Of these, fifty were reported as normal, fifty-two suffered from carcinoma of the stomach and fifty-one showed the presence of gastric ulcer (Figs. 1 and 2).

In seven patients the roentgenologist reported suspicion of carcinoma. However, the intragastric pictures were definitely positive. Three of these patients were operated upon and the diagnosis proven in each case

In the remainder of our series, both methods differed in their diagnostic pointings. In fifteen of these patients, the intragastric pictures showed the presence of *ulcer*, most of which were quite shallow (Fig. 3). Thirteen of these patients were roentgenographed with the diagnosis of pyloric carcinoma in two and with negative results in the remainder (Figs. 4 and 5). Three of this series were operated upon and the diagnoses by intragastric photography were confirmed. In the remaining ten patients, the diagnosis was substantiated by the history and subsequent clinical course.

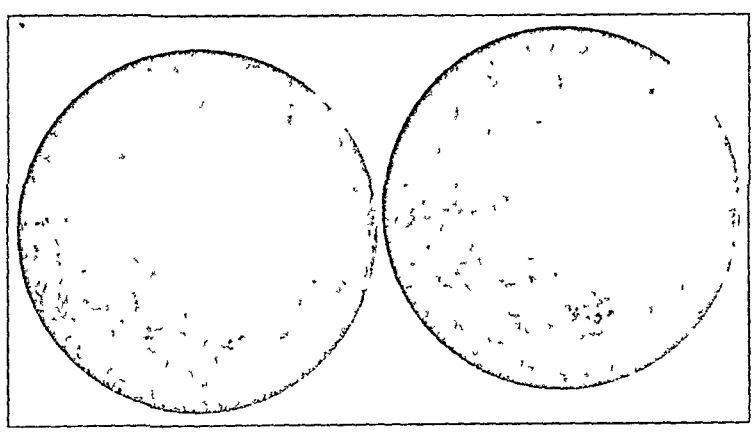

Fig. 5 Picture shows ulcer on lesser curvature. X-ray diagnosis carcinoma on lesser curvature At operation ulcer was found. Note rugae radiating from the ulcer in fan shape.

Chronic gastritis was diagnosed twenty-eight times. In twenty-seven instances the roentgenographic reports were negative. In one patient the report was carcinoma of the stomach. Operation proved the presence of marked hypertrophic gastritis with no evidence of carcinoma. The patient is alive and well two years after the operation (Fig. 6).

Fig. 6. Pictures show chronic gastritis. X-ray examination showed large defect on greater curvature, interpreted as carcinoma. Operation proved absence of carcinoma and presence of chronic gastritis. Defect was due to band constricting greater curvature.

Three patients affected with gastric carcinoma were correctly diagnosed by intragastric photography. This observation was proven by operation on two patients; the third died with evidence of carcinoma and metastases. In two of these subjects, the X-ray diagnosis was gastric ulcer; in one "no defect" was noted (Fig. 7).

On the other hand, in eight patients the roentgenographic examination showed the presence of ulcer which was not the finding from intragastric photography. One of these patients was operated upon but no ulcer was found.

In two patients who had been operated previously for gastric ulcer and a gastro-enterostomy performed, in each case, the roentgenograph showed patent stomata. The intragastric pictures, however, failed to reveal the site of the gastro-enterostomy. This may have been due to poor technique in locating the camera.

COMMENT

From the above studies, it may be concluded that intragastric photography is a valuable adjunct as a diagnostic procedure in all cases of suspected or of obscure gastric lesions. As reported above, it has demonstrated its usefulness in cases where lesions were suspected but could not be proven by roentgen methods. Shallow mucosal ulcers often readily were demonstrated by the intragastric camera when such were not even suspected after the roentgenogram examination.

Intragastric photography should prove useful in the diagnosis of early gastric tumors, especially malignancies, at a stage when it is difficult to demonstrate such lesions by roentgenography. The procedure is a very useful aid in the diagnosis of chronic gastritis, whereas roentgenograms practically are of no value in that condition. By this new diagnostic method we are enabled to photograph the living mucosa directly and consequently should be able to establish the presence of objective damage. In our series of patients, frequently we were able to diagnose chronic gastritis,

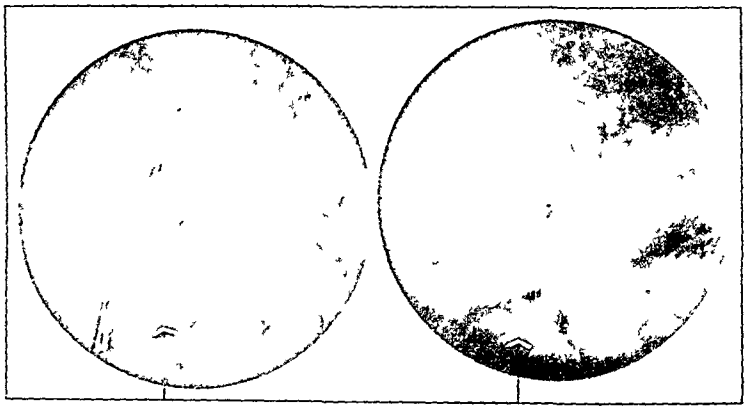

Fig. 7. Picture shows presence of tumor near pylorus. X-ray report was stenosing ulcer at pylorus. Operation proved presence of carcinoma.

often with superficial mucosal ulcerations, existing either as a clinical entity, or associated with such other pathological conditions as gastric and duodenal ulcer and cholecystitis. It should be possible to differentiate the atrophic from the hypertrophic type of chronic gastritis by means of these photographs. (Footnote).

However, it will take considerable time to fully appreciate the value of intragastric photographs and the method itself. As our experience increases, the technique will be greatly improved and our ability more complete to interpret the resultant pictures and to diminish the errors in diagnosis previously made. In this respect, intragastric photography is comparable with roentgenography in its early phases of clinical use. It is not expected that the procedure ever will replace the roentgen ray or other well established clinical methods used now in the examination of the stomach but it should prove of great help in more clearly or definitely making diagnoses in obscure instances.

Footnote: If the films or the prints, obtained by intragastric photography, are studied carefully by a hand glass giving moderate magnification, interesting and not altogether unimportant, additional pathologic changes become evident.—*Editor.*

The Origin, Fate and Significance of the Serum Enzymes

By

ANTON W. OELGOETZ, M.D.
PAUL A. OELGOETZ, B.A.
and
J. WITTEKIND, R.N.
COLUMBUS, OHIO

BECAUSE they play an important rôle in normal digestion, and because, unquestionably, they are a factor in the etiology of food allergy, the pancreatic enzymes are assuming an increasing significance in the diagnosis and treatment of gastro-intestinal disturbances. There is need for a practical, reliable test for determining the function of the pancreas. Differences in methods, tests, terminology, and a lack of normal standards, are some of the reasons why a test for determining the pancreatic index is not now routine practice. In other papers (1, 2) we have given our reasons why we do not believe that any test for determining the pancreatic function, based upon a determination of the concentration of enzymes in the duodenal secretions, can give a true picture of the total, daily secretion of the pancreas. We have shown that, in health, the blood always contains the three pancreatic enzymes in a definite and constant concentration, and it is only in the serum that we can accurately determine the pancreatic index.

Likewise, the question of the therapeutic value of the pancreatic enzymes when given by mouth, is in a state of confusion. Elman and McCaughan (3) for example, do not believe that absorbed amylase plays a part in maintaining the serum level of amylase. Zucker, Newberger and Berg (4) deny the absorption of amylase. Crandall (5) believes that absorption of minute quantities of amylase is probable. These reports are precisely contrary to our findings. We have found that all three pancreatic enzymes are completely absorbed, even when given in excessive dosage (200 grains of an active extract, containing all three enzymes). Our findings have been so definite and we have obtained the same results so many times, that we believe that these differences can only be due to differences in tests and methods employed.

Crandall's work was done principally on dogs with fistulae. In our opinion any external opening destroys the "closed system" upon which depends the pancreatic secretory mechanism. We have evidence which indicates that the normal secretion of the pancreas is regulated by a mechanism dependent upon a chemical equilibrium between the concentration of enzymes in the blood, and the concentration within the cells of the pancreas. When the serum concentration of enzymes falls below 0.2 by our test, enzymes pass from the pancreas into the blood stream; when the serum concentration reaches 0.2, the concentration in the blood and within the cells of the pancreas is in equilibrium and secretion ceases. This work will be fully reported in a later paper.

In former days, surgeons observed the rule: "When in doubt, always drain," but latterly they are commencing to appreciate the fact that prolonged, unnecessary drainage, because it carries out normal secretions, thereby upsetting the delicate chemical equilibrium by which glandular secretion is regulated, very often is the factor which makes for a fatal outcome. Studies made on frightened, injured, frequently infected animals, with the pancreatic secretory mechanism "open", cannot be expected to give a truly normal picture of the pancreatic enzyme concentration. Zucker, Newberger and Berg used the starch-iodine test (Wohlgemuth) which in our opinion, is worthless as a quantitative test for enzyme concentration. Most of our work was done on patients who were not disturbed more than is necessary to obtain blood from a vein. The taking of a small quantity of blood from a vein at the elbow, is so quickly and easily done, that the delicate secretory mechanism is unaffected, and we

Submitted, January 7, 1936.

obtain a truly normal picture of the enzyme concentration in the serum.

In this paper we will briefly restate our position, report additional information not hitherto published, review the salient features of our test, and thus attempt to dissipate the confusion which now surrounds pancreatic diagnosis and therapy. It is only in this manner that we can ever hope to rationalize our differences, which we believe, can only be the result of differences in procedure.

THE ENZYMES IN NORMAL SERUM

Normal serum always contains serum amylase, which hydrolyzes all starches; serum lipase which splits all fats, and serum protease which hydrolyzes all proteins. These three enzymes are always found in a definite and constant concentration, which is uninfluenced by intake of food, sleep or exercise. Likewise, the serum enzymes are always found in parallel concentration, i.e., if one of them is present in a certain concentration, all are present in the same relative concentration. The normal serum concentration of serum enzymes is 0.2 by the test which we have suggested. In previous papers (1, 2) we have stated our belief that the pancreas normally secretes a sufficient concentration of enzymes to combine with all of the food taken, plus an excess which passes free into the blood stream. It is the concentration of these free serum enzymes which is determined by our test. Every cell in the body is thus protected against whole, unracemized foods by these buffer serum enzymes, which prevent any food from reaching the cells in an unsplit state which cannot be used as food.

METHODS

In our opinion, the best test for amylase is a determination of the reducing sugar liberated from a given quantity and percentage solution of soluble starch by 0.2 c.c. serum, when incubated at body temperature for a given period. The menstrum, of course, must be correct for optimal enzyme activity. This test, however, is only accurate when a spot test is finally made to determine accurately the end-point when reduction of Fehling's solution is complete. (One drop of solution to be tested; one drop of 5% acetic acid; plus one drop of 10% potassium ferrocyanide. Incomplete reduction of copper gives a brown film.)

The concentration of lipase is determined by finding the quantity of fatty acid set free when 0.2 c.c. serum is incubated at body temperature for a given period with ½ c.c. of any neutral food oil (corn or olive oil). The quantity of acid is determined by titrating against .02 normal sodium hydroxide. The concentration of trypsin is determined by finding the quantity of fibrin which is completely hydrolyzed by 0.2 c.c. serum when incubated at body temperature for a given period. For this purpose, we fashion fibrin into cylinders of standard length and diameter, by mixing powdered fibrin with warm water and pressing the mass through a glass pipette. The cylinders are standardized by determining the length of cylinder which is completely hydrolyzed by 0.2 c.c. normal serum when incubated at 98.6 for 24 hours.

But because the serum enzymes are always secreted in parallel concentration, previously pointed out by us and later verified by Baxter (6) the serum concentration of enzymes can be more easily and accurately determined by finding the concentration of amylase alone. If amylase is present in a certain concentration, all three pancreatic enzymes are present in the same relative concentration. Because there exists confusion concerning the difference between our test and the older starch-iodine test, we will at this point, briefly restate the technique of the newer test. The test, together with a discussion of the involved chemistry, has been described in detail elsewhere (7).

Test for Determining the Pancreatic Index (Test for Food Allergy)

The reagent: Make a 5% suspension of *starch cells (Argo) in distilled* water. To each ounce add 4 drops of Lugol's solution from a medicine dropper. Shake. Under the microscope the starch cells will be seen stained blue-black, each cell containing a definite quantity (the "just right" quantity) of starch-iodine compound.

The test: To each of six small test tubes, add 1 c.c. reagent. To successive tubes add respectively, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6 c.c. serum. Shake and incubate for 24 hours in the warm air incubator (not the water bath) at 98.6.

The reading: When the test is set up as above, the starch cells settle to the bottom of the tube in a black mass. That tube in which the black mass at the bottom of the tube *turns completely white* in 24 hours is the reading. The normal pancreatic index by this test is two-tenths (0.2). The number one tube is the control. If the number 6 tube turns completely white, while the other tubes still contain varying quantities of black at the bottom, the reading is *minus* 4 (6 minus 2 equals minus 4). If the number two tube "goes over" (turns completely white) the serum enzymes are present in normal concentration and the patient is not allergic to food. On the other hand, a pancreatic index of minus 4 indicates that the serum enzymes are present in reduced concentration and the patient is allergic to food. Because the serum enzymes are always present in a constant concentration, blood may be taken at any time.

It will thus be seen that the newer test differs from the older test in that the iodine is fixed by the starch until liberated by the amylase, when it immediately combines with the intermediate products of hydrolysis. Because free iodine is never present, the reaction continues on to completion. The test is a moving titration of hydrolysis as it proceeds—in the test tube and also in the blood stream.

In the older test, when used quantitatively, it is impossible to distinguish between the colors imparted by small quantities of starch and iodine, and the color imparted by iodine itself; while in our test the color changes are distinct—from jet black to white. The newer test is a cross section of hydrolysis as it takes place in the blood stream; a cleancut, visual method for titrating hydrolysis from beginning to end.

ARE SERUM ENZYMES PANCREATIC ENZYMES?

Enzymes which are functionally identical with the pancreatic enzymes, are found in the serum, urine, feces, and in extracts of every organ and tissue of the body, except the heart and brain. That all of these enzymes are pancreatic enzymes would seem to be indicated by the fact that their concentration can be influenced by the administration of an extract of whole pancreas. The normal serum concentration of enzymes is 0.2 by our test, and cannot be made to go above this level. If a patient with a pancreatic index of minus 4 is given 10 grains of an extract of whole pancreas, the serum concentration is restored to normal in one hour. If a massive dose (200 grains of the whole extract, containing all three enzymes) is given at one time, to a patient with a normal index, and hourly titrations of serum and urine made, it will be found that the serum concentration remains normal, while the urinary concentration falls approximately 50% in one hour. These observations indicate a definite relationship between the exhibition of pancreatic extract and the serum and urinary concentrations of en-

zymes. The prompt manner in which an active extract of whole pancreas influences the blood and urinary enzyme level, would seem to indicate that the pancreatic enzymes are absorbed from the gastro-intestinal tract, and that the serum and urinary enzymes are in fact, pancreatic enzymes.

THE ABSORPTION OF PANCREATIC ENZYMES

That the pancreatic enzymes, when given by mouth, are absorbed in the active state, would seem to be indicated by the following observations. If 10 grains of an active extract of whole pancreas is given to a patient with the highest degree of pancreatic hypofunction, (minus 4) the serum concentration will be restored to normal in one hour. Thereafter, it will gradually fall to the previous level. If a larger dose is given (50 grains), the serum level will be restored to normal in one hour and remain normal for approximately three days, when it will gradually fall to the original level. These observations indicate that pancreatic extract is absorbed, and that when taken in quantities in excess of that necessary to restore the normal serum level, the excess is stored, and later liberated in such concentration as to maintain the normal serum level. The serum level cannot be made to go above two-tenths (0.2) by our test. When the larger dose is given (50 grains) the urinary concentration always falls approximately 50% in one hour, while the concentration in the feces is unaffected. In short, when given to a patient suffering from pancreatic hypofunction, pancreatic extract restores the normal serum enzyme level; when given to a normal patient, the serum level is unaffected. Likewise, the concentration in the feces is unaffected, while the urinary concentration is reduced. These observations indicate that the pancreatic enzymes are not eliminated in the urine or feces. We do not believe that the enzymes are eliminated by any channel, in the sense that truly foreign substances are eliminated from the body. If the urinary enzymes were true excretion products, an increased intake of enzymes would be followed by an increase in the urinary concentration. Their presence in the feces can easily be accounted for, but we have no explanation as to the significance, if any, of the decrease in the urinary concentration, following administration of large doses of pancreatic extract. Evidently, the kidneys exhibit toward the enzymes a selective permeability, which decreases in the presence of an increased concentration of enzymes.

THE RELATION OF THE SERUM ENZYMES TO THE SPLEEN AND LIVER

As stated above, if 50 grains of pancreatic extract are given to a patient with a normal pancreatic index, the serum concentration remains unaffected; the concentration in the feces remains unchanged, while the urinary concentration decreases. What then becomes of the extract? Is it destroyed—digested, so that we no longer find the enzymes in the active state, but in a form which is indistinguishable from other proteins? Are they stored somewhere in the body? In order to determine this last possibility, the following experiment was undertaken.

One group of rabbits from the same litter were given 30 grains of pancreatic extract daily for one week. The animals then were sacrificed and, together with control animals, all organs were ground with quartz sand and extracted with distilled water. The extracts were neutralized and titrated for enzyme concentration by the methods previously outlined. The concentration of enzymes in the livers of those animals which had received pancreatic extract in excessive dosage, was approximately twice that in the control animals, while the spleen contained a concentration averaging 17 times greater than the control animals, indicating that when given in excessive dosage, the pancreatic enzymes are stored in the active state in the liver and spleen. The fact that the serum concentration remains normal for several days when a subnormal patient is given an excessive dose of pancreatic substance, would seem to indicate that the stored enzymes are released from the spleen and liver in such concentration as to maintain the normal serum concentration.

Finally, we will close by asking a question. It has been definitely shown by a number of workers (Alvarez, Walzer, etc.) that whole proteins normally pass into the blood stream and are regular and normal constituents of serum. What then becomes of them? What, normally, is their ultimate fate? Why are we not all food sensitive all of the time? We believe that the serum proteins are split by the serum enzymes, and that a reduced serum enzyme concentration explains allergy to foods. Clinically, the administration by mouth, of an active extract of whole pancreas, has been found to be effective by the writers, and by a number of other careful clinicians.

CONCLUSIONS

1. Normal serum always contains serum amylase, lipase and protease, in a constant concentration of 0.2 by the test which we have suggested.
2. We believe we have shown that the serum enzymes are in fact, pancreatic enzymes.
3. When given by mouth, the pancreatic enzymes are absorbed in the active state.
4. The normal concentration of serum enzymes cannot be increased by the administration of pancreatic enzymes.
5. Pancreatic hypofunction is quickly corrected by the administration of an active extract of whole pancreas.
6. When given in excessive dosage, pancreatic extract seems to be stored in the liver and spleen, from which organs it is liberated in such concentration as to maintain the normal serum level.

Daily Variations in the Concentrations of Acid and Pepsin in the Gastric Juice of Three Persons Observed for Two Months*

By

WALTER C. ALVAREZ, M.D.†
FRANCES R. VANZANT, M.D.**
and
ARNOLD E. OSTERBERG, Ph.D.‡
ROCHESTER, MINNESOTA

FOR fifty years and more physicians have been depending for diagnostic aid on a single gastric analysis, seldom stopping to find out how different the figures might be if a second or a third analysis were to be made on successive days. In 1931 we tried to fill this gap in medical knowledge by studying the variations in acidity which took place in the gastric juice of two young women observed daily for a month (1).

One of these women, who was nervously stable, had a fairly constant gastric acidity except at the end of the period of observation, when she became excited over the prospect of her approaching vacation trip. Then there was a big variation from her normal. The other young woman, who was less stable emotionally, reacted to a severe disappointment with large swings up and down in the curve representing gastric acidity. As a result, there were many days during the month when a single gastric analysis would have been worse than useless as an index to the normal activity of her gastric mucosa.

Recently, while studying the effect of a diet deficient in vitamin B_1, the senior writer had the opportunity of studying for two months the concentrations of acid and pepsin in gastric juice removed almost every day from the stomachs of two women and one man. The nutritional aspects of this experiment will be described elsewhere, and in this place we will record only the extent of daily variations in the gastric juice, together with a few other data. Because the deficient diet did not seem to have any effect on gastric secretion, it seems probable that the daily variations observed in these three persons closely resemble those that might be found in anyone living on a normal diet.

In Figure 1, the three sets of curves represent concentrations of acid and pepsin in gastric juice obtained from the three persons studied. It will be seen that with both acid and pepsin there was least variation in the case of the man, Dr. P. Interesting is the fact

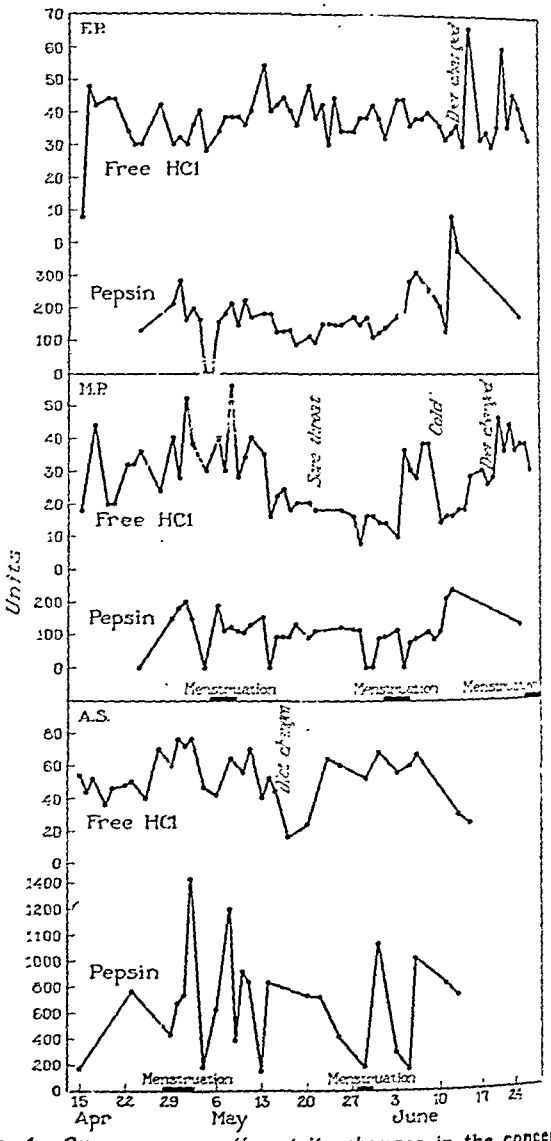

Fig. 1. Curves representing daily changes in the concentration of acid and pepsin in the gastric juice of three persons studied for two months

Submitted November 15, 1933.

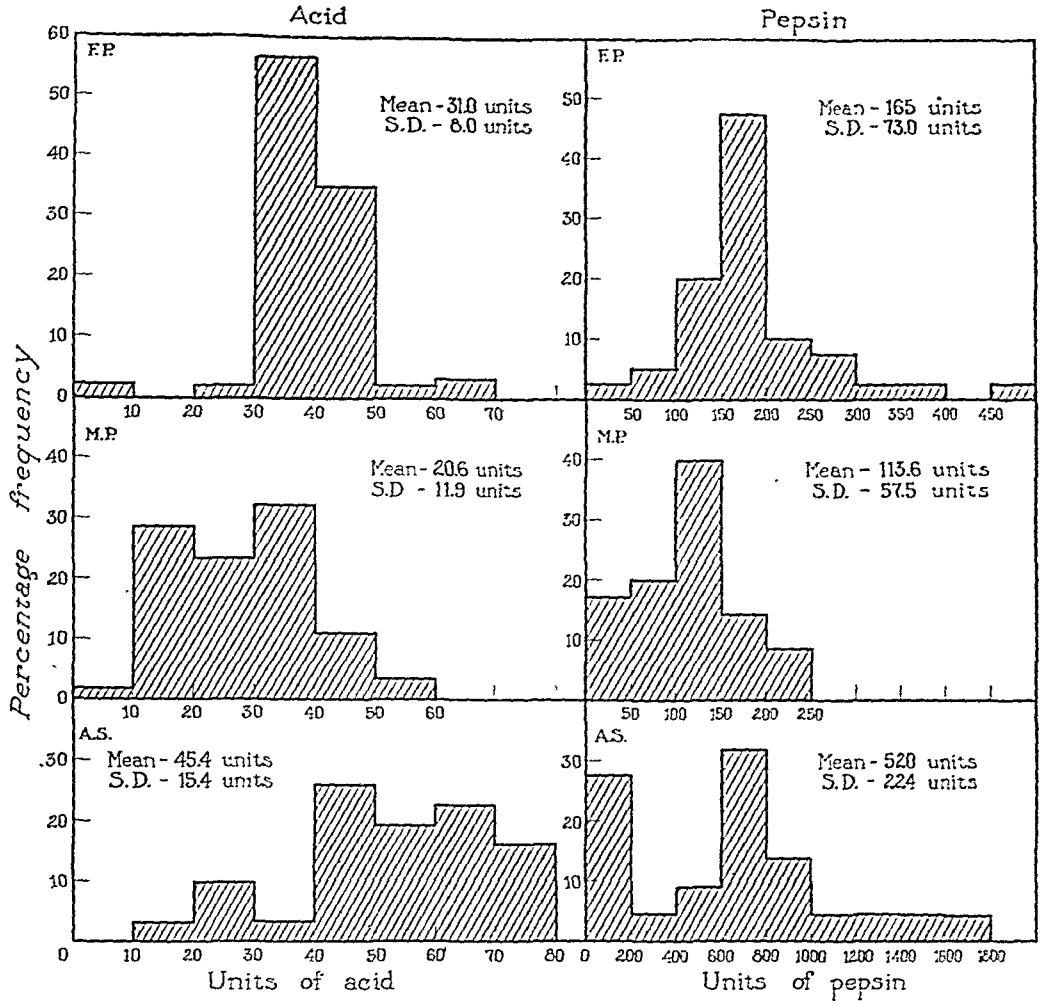

Fig. 2. Polygons showing for each of the three persons studied percentage distributions of the concentrations of acid and pepsin found in the gastric juice.

that in his case, the first measurement of acidity made, and the only one which would ordinarily have been available to a physician examining him, was very low and different from all subsequent values obtained. Interesting also is the fact that there were spectacular rises in the concentrations of pepsin and acid when this man, who for six weeks had been hungry, was told that he could stop the experiment and eat all he wanted.

In the case of Mrs. P. the two marked drops in acidity were associated with respiratory infections. We have as yet no explanation for the one big upward swing in the curve representing concentration of pepsin.

Miss S. was markedly tempermental, and the curves representing concentration of acid and pepsin in her gastric juice seem to reflect, in their irregularity, her mercurial nature. In her case, the curve representing concentration of pepsin is much more irregular than that representing acidity.

Incidentally it may be worth noting that, in the case of this woman, each of the three marked dips in the curve of free acidity appeared about eleven days before the onset of a menstrual period. There was no sign of any such cyclic difference in the gastric acidity of either Mrs. P. or of the two women studied by us in 1931.

Figure 2 shows the distributions of the concentrations of acid and pepsin observed in the case of the three persons. There, from simple inspection, it appears that data from Dr. P. showed the least variation; data from Mrs. P. came next, and data from Miss S. came third, with the greatest variation.

For concentrations of pepsin, the standard deviations in the three cases were 73, 57.5, and 224, respectively. The fact that these values are about half the size of the corresponding means shows again how wide the variation is when pepsin is measured repeatedly in one person. For acidities, the standard deviations were 8, 11.9, and 15.4. In the case of the two persons studied in 1931, the corresponding figures were 6.6 and 8.7.

Although at first glance there seemed to be little if any correlation between the concentrations of acid and pepsin in a single sample of juice, calculation showed coefficients of correlation of +0.528, +0.124, and +0.360 for data from Dr. P., Mrs. P., and Miss S., respectively.

SUMMARY

There were marked daily variations in the concentration of acid and pepsin in the gastric juice of three

persons who were studied almost every day for a period of two months. At times when these variations were great, one gastric analysis or even three or four made on successive days would have given a decidedly misleading idea of the usual ability of the particular stomach to secrete acid and pepsin.

The variability in gastric secretion was different in three persons studied. The evidence suggests that the greatest degrees of variability are to be found in nervous, impressionable, and temperamental persons who react too much to their environment.

It is conceivable that the big daily changes in the digestive power of the gastric juice which take place in nervous persons can at times have deleterious effects on the mucous membranes of stomach and duodenum.

The Influence of Mucoitinsulfuric Acid on Peptic Digestion*

By

S. A. KOMAROV, M.D., Ph.D.
MONTREAL, CANADA

IT was recently reported that peptic digestion can be greatly inhibited by commercial "gastric mucin" and by chondroitinsulfuric acid (Babkin and Komarov, 1932; Bradley and Hodges, 1934; Zaus and Fosdick, 1934). On the other hand, sufficiently purified preparations of mucoproteins, such as submaxillary mucin and mucin isolated from the alkaline or neutral gastric secretion of a fasting animal, failed to inhibit peptic activity in the early stages of digestion. Some inhibition could be observed, however, after more prolonged incubation.

Commercial "gastric mucin" was found to be a very composite mixture of many substances—chiefly products of the peptic digestion of mucoproteins—and appeared to be especially rich in mucoitinsulfuric acid. As a hypothetical explanation of the above observations the theory was advanced (Babkin and Komarov, *l.c.*) that the agent responsible for the strong inhibitory action of commercial "gastric mucin" on peptic digestion is mucoitinsulfuric acid and that the delayed inhibition of peptic digestion observed in experiments with purified mucoproteins is also due to the liberation of the same substances in the course of digestion. However, up to the present no direct evidence in this respect has been available owing to the difficulties experienced in obtaining sufficiently pure preparations of mucoitinsulfuric acid from gastric mucus.

According to Levene (1925) chondroitinsulfuric acid is a body closely related to the group of mucoitinsulfuric acids, yet these two groups of conjugated sulfuric acids are *intrinsically distinct*. Moreover, even in the group of mucoitinsulfuric acids the individual representatives exhibit decided differences in their properties. It is obviously important to ascertain the effect which the particular mucoitinsulfuric acid derived from gastric mucin would exert on peptic digestion. The need for such a study is accentuated by the fact that mucoitinsulfuric acid has recently been demonstrated (Komarov, 1935) to be an integral part of the protein complex of canine gastric juice.

*From the Department of Physiology, McGill University.
Submitted January 16, 1936.

MATERIAL AND METHODS

The present report is based on a study of the effects produced on peptic digestion by four preparations of mucoitinsulfuric acid. One of the preparations was isolated from gastric juice in the form of sodium salt (preparation 1 of Komarov, 1935). The other three preparations were isolated in different ways from commercial gastric mucin (*Wilson Laboratories*). The methods of isolation and a full account of the analytical data will be reported elsewhere. All our preparations exhibited the general properties characteristic of mucoitinsulfuric acid derived from gastric mucus, as described by Levene (1925). It should be especially emphasized that they did not give the biuret reaction and did not contain phosphorus. The values for C, H, N and S were found to be entirely within the range for the preparations of mucoitinsulfuric acid obtained from various sources, as reported in the literature (Levene, 1925; Lopez-Suarez, 1913; Alzona, 1914). The only material difference in the composition of our preparations was in the content of sulfur, this being 5.04, 1.65, 1.30 and 1.01 per cent for preparations 1, 2, 3 and 4 respectively. These data indicate that the above preparations are mixtures of mucoitinsulfuric acid and mucoitin in varying proportions. On the basis of their sulfur content these preparations can be regarded as consisting respectively of 74, 24, 19 and 15 per cent of mucoitinsulfuric acid, the rest being mucoitin.

As sources of pepsin several commercial preparations of pepsin (Parke, Davis, U. S. P. 1:3000 and 1:10000; and Merck) were used, as well as various samples of canine gastric juice collected under different conditions of stimulation from dogs with a Pavlov pouch or with a gastric fistula and oesophagotomy. The peptic activity was determined either by Mett's method or by titration after Willstätter and Waldschmidt-Leitz (1921). In the latter case the substrates used were soluble egg-albumen (Merck) and solutions of acid metaproteins prepared from egg-white. In most of the experiments preparations 2, 3 and 4 of mucoitinsulfuric acid were converted into sodium salt immediately before use by dissolving in distilled water and neutralizing with NaOH to pH 7.0. In the control samples, instead of mucoitinsulfuric acid, distilled water was used, or solutions of sodium sulfate and sodium chloride in amounts equivalent to the content of sulfates and chlorides as determined in the ash of the corresponding preparations. In all the experiments the titratable acidity or the pH was equalized, the latter by means of Sörensen's

(1912) M/10 citrate buffer solutions. Nearly a hundred such experiments were carried out; only a few typical examples are presented here as illustrations.

EXPERIMENTAL RESULTS

The main fact revealed by this investigation is that mucoitinsulfuric acid inhibited the peptic activity of all the commercial pepsin preparations so far studied

TABLE I

Experiment of May 2nd. Pepsin (Parke, Davis & Co., U.S.P. 1:10,000) and mucoitinsulfuric acid (preparation 3) were used. These substances, in quantities as shown, were dissolved in 10 c.c. of M/10 citrate buffer solution, pH 2.0. The peptic power was measured by Mett's method.

Sample	Pepsin mg.	Mucoitin-sulfuric Acid mg.	Peptic Digestion 20 hrs at 38° C. sq. of mm.	Inhibition % of control
1	10.0	15.0	7.3	19.0
Control	10.0	none	9.0	—
2	5.0	15.0	2.9	34.0
Control	5.0	none	4.4	—
3	2.5	15.0	1.4	39.0
Control	2.5	none	2.3	—

and of most of the samples of gastric juice. The effect of mucoitinsulfuric acid on the proteolytic activity of commercial preparations of pepsin is illustrated in Table I. Similar results were obtained with the other preparations of pepsin studied.

More attention, however, has been paid in this study to the effect of mucoitinsulfuric acid on the peptic activity of canine gastric juice. Certain differences were found in the action of our four preparations of mucoitinsulfuric acid in this respect. All these preparations, when added in doses of a few milligrams per 1 c.c. of gastric juice, produced as a typical effect a marked inhibition of the peptic activity; but the degree of inhibition thus exerted was found to depend on the purity of the preparations. The preparation with the greatest inhibitory power was preparation 1, which was isolated from gastric juice and contained 74

TABLE II

Experiment of July 25th. 10 c.c. of gastric juice were diluted with 80 c.c. of 0.05N HCl and 10 c.c. of 0.5N HCl. 10 c.c. of this mixture were added to each of the samples described below. The acidity was equal in all the samples, viz., total 66, free 56 m. eq. per l.

per cent of mucoitinsulfuric acid and 26 per cent of mucoitin. The activity of this preparation was identical with that of chondroitinsulfuric acid (a preparation kindly supplied by Dr. P. A. Levene of the Rockefeller Institute). This is illustrated in Table II. Preparations 2, 3 and 4 were less active than chondroitinsulfuric acid, yet they were many times more active than commercial gastric mucin, from which they were isolated. These relations are illustrated in Table III. Our general conclusion from the whole series of similar experiments is that the inhibitory activity of the above preparations depends on their content of ethereal sulfates, the preparations containing more sulfur being decidedly more active in this respect. This indicates that only unbroken mucoitinsulfuric acid possesses a strong inhibitory power, whereas the first product of its hydrolysis—the mucoitin devoid of the radicle of sulfuric acid—inhibits the peptic activity to a lesser extent or perhaps does not inhibit it at all.

The inhibitory action of mucoitinsulfuric acid on peptic digestion does not depend materially on the physicochemical properties of the substrate. It could be observed not only in the cases where coagulated egg-white was used as a substrate (as in Mett's method) but also where solutions of egg-albumen or

TABLE III

Experiment of February 11th. Gastric juice was obtained from two dogs with a gastric fistula and oesophagotomy by means of sham-feeding. The water-clear secretion was filtered immediately and preserved in the ice-box for two days. For the experiment it was diluted with two parts of 0.025N HCl. 15 c.c. of this mixture were added to each of the samples described below.

Sample	Substance	Acidity Total	Acidity Free	Peptic Digestion 24 hrs at 38° C. sq. of mm.	Inhibition % of controls
		m. eq./l.

5	20 mg. Na salt of chondroitin-sulfuric acid	65	52	13.7	49.5

of acid metaproteins were employed and the rate of digestion was determined by the method of Willstätter and Waldschmidt-Leitz.

When varying quantities of mucoitinsulfuric acid are added to the same amount of gastric juice, the degree of inhibition of the peptic activity is the greater, the greater the concentration of mucoitinsulfuric acid, but only up to a certain point, beyond which further increase in the concentration of mucoitinsulfuric acid is not accompanied by any additional increase in the inhibitory effect (see Table IV). In this connection it should be mentioned that in not a single experiment was the peptic activity entirely inhibited by mucoitinsulfuric acid even when relatively large quantities of this substance were used (e.g. 50 mg. to 1 c.c. of gastric juice containing 1.2 to 1.5 mg. of protein).

Although mucoitinsulfuric acid had a striking inhibitory effect on the peptic activity of all the commercial preparations of pepsin so far investigated, and of most of the samples of canine gastric juice, yet in certain kinds of gastric juice the peptic activity could not be inhibited at all. The samples of gastric juice

obtained in response to subcutaneous injections of histamine (in doses of 0.05 mg. per 1 kg. weight) were found to be especially resistant. Another kind of gastric juice, the peptic power of which frequently could not be inhibited by mucoitinsulfuric acid, was the secretion collected at the very beginning of sham-feeding and the very last portions of the secretion thus induced; these samples usually contained large amounts of visible mucus.

DISCUSSION

The sum of the experimental evidence at present available indicates that the inhibitory effect, which mucoitinsulfuric acid exerts on the peptic activity of commercial preparations of pepsin and of gastric juice, does not materially depend on its action on a substrate but is due rather to its action on the enzyme. The strongest arguments in favor of such a view are the facts that the degree of inhibition which could be produced by increasing quantities of mucoitinsulfuric acid had a definite limit for every particular kind of gastric secretion, and that the peptic activity of certain types of gastric juice could not be inhibited at all by this substance. Why certain kinds of gastric juice, in respect of their peptic activity, are resistant to the action of mucoitinsulfuric acid is not yet entirely understood. The investigation of this problem is being continued. Some data are available, however, with regard to the secretion provoked by histamine, which was found to be especially resistant in this respect. It was found (unpublished experiments of the writer) that the protein material present in the histamine gastric juice has a more pronounced mucin-like character than that of the secretion induced by sham-feeding. The former was found to contain in all the cases so far investigated a smaller percentage of nitrogen (about 12 per cent) and to show a higher reduction after acid hydrolysis (an average of 30 per cent glucose). Apparently, in this case, pepsin is already linked to mucoitinsulfuric acid and therefore is unable to react with additional amounts of this substance.

Evidence has been obtained (Webster and Komarov, 1932; Babkin and Komarov, 1932) that in normal, freshly secreted gastric juice, pepsin may be present as a mucoprotein or as a complex compound with mucoprotein. This hypothesis is further supported by the fact that mucoitinsulfuric acid has been isolated in considerable amounts from the gastric juice and also from the protein fraction of this secretion (Komarov, 1935).

In view of the above considerations it seems reasonable to conclude that mucoitinsulfuric acid plays an important *rôle* in the regulation of the peptic activity of the gastric juice.

TABLE IV

Experiment of August 13th. Gastric juice was collected from a dog with a gastric fistula and oesophagotomy after sham-feeding. It was immediately filtered and mixed with four volumes of 0.05N HCl. 10 c.c. of the mixture were used in each sample. Preparation 2 of mucoitinsulfuric acid was used as free acid in the amounts shown.

Sample	Mucoitinsulfuric Acid mg	Acidity Total (m eq./l.)	Acidity Free (m eq./l.)	Peptic Digestion 24 hrs. at 38° C. sq. of mm.	Inhibition % of controls
Control	none	78	58	27.0	—
Control	none	78	58	27.0	—
1	10	79	58	16.8	37.8
2	20	80	58	16.0	40.7
3	30	81	58	16.0	40.7
4	40	82	58	16.0	40.7
5	50	83	58	16.0	40.7

SUMMARY

Mucoitinsulfuric acid, isolated from canine gastric juice or from commercial gastric mucin, inhibits the peptic activity of various commercial preparations of pepsin and in most cases also the peptic activity of gastric juice. The mechanism of this effect and the possible *rôle* of the mucoitinsulfuric acid present in the gastric juice are discussed.

The writer gratefully acknowledges the helpful criticism and advice which he has received from Professor B. P. Babkin during the course of this work.

Pyloroplasty, Gastroenterostomy and Partial Parasympathetic Denervation of the Pyloric Sphincter, and Their Relation to the Emptying Time of the Stomach*

By

GEORGE CRISLER, M.D., Ph.D

and

E. J. VAN LIERE, M.D., Ph.D.

MORGANTOWN, WEST VIRGINIA

ALTHOUGH resection of the pyloric sphincter has been widely and successfully employed to shorten the emptying time of the stomach in cases of pyloric obstruction since before the report of Rammstedt (1), (2), (3), (4), controlled experiments done by different authors on the emptying time of the normal stomach after such and similar operations have led to conflicting reports. McCann (5) has rightly said that "a half century of experimentation has not solved the problem of the emptying of the stomach." From his experiments on dogs he implicated the entire pyloric portion of the stomach as the important mechanism for the gastric retention of food, but admitted that the sphincter was the most important part of it. His procedures involved resecting the pyloric sphincter for a distance of two to two and one-half centimeters. He found that such an operation served to retain less food in the stomach, "indicating that the efficiency of the mechanism for the proper retention of the meal had been impaired." Pannett (6) found after simple resection of the pyloric sphincter in cats that food passed into the duodenum more quickly and in greater amounts during the early stages of digestion, but he was unable to state whether or not this acceleration of the passage of food from the stomach was maintained until it was empty. Thompson (7) working on the effect of resection of the pylorus in dogs states, "Following resection of portions of the pylorus, the emptying rate was reduced below the preoperative emptying time, regardless of the grade of resection. The rate, however, was not reduced increasingly for each grade of resection. Absence of the pyloric sphincter, therefore, rather than the increase in diameter of the pyloric outlet, seems to be responsible for the result observed." Later in the same paper, however, he states, "Contrary to prevailing opinion and despite the fact that the pyloric sphincter regulates the emptying of the stomach and the admission of duodenal juices into it, resection of the sphincter, combined with Polya gastrojejunostomy, does not lower the acidity of the gastric content nor hasten emptying of the stomach. . . . The fact that widening of the outlet of the stomach does not shorten its emptying time is also contrary to the general conception." Hughson (8) reported that section of the vagus nerves in dogs either at the cardia or on the anterior and posterior walls of the stomach caused a decrease in the normal emptying time of the stomach under general experimental conditions. Fetter, Barron and Carlson (9) reported a distinct delay in gastric evacuation of dogs after section of the vagi just below the diaphram. Meek and Herrin (10) found that the average emptying time was at least three times as long as the preoperative normal emptying time after intrathoracic resection of the vagi at the level of the seventh rib.

The present paper contains data, which are a by-product of another series of experiments, showing that in dogs simple resection of the pyloric sphincter, supplementing it by gastro-enterostomy, or partially parasympathetically denervating it does not shorten the emptying time of the normal stomach, but rather, if anything, lengthens it.

METHOD

In nine dogs the averages of from 5 to 17 normal gastric emptying times per dog were determined fluoroscopically using the experimental diet we have used in all of our experiments on gastric emptying times (11), (12). The pyloric sphincters were then sectioned (Rammstedt operation) and the average emptying times were re-established. In five dogs after the average control emptying time was determined for each animal a posterior gastro-enterostomy was performed and the emptying time was again determined. It two of these dogs (B-II and B-IV, Table I) the pyloric outlet was ligated at the time of the operation; in the others it was left patent. In one dog the emptying time was determined before and after partial parasympathetic denervation of the pyloric sphincter. The denervation was accomplished by rimming around the stomach a centimeter proximal to the pyloric sphincter down to the mucosa and placing four anchor stitches to prevent undue retraction of the cut structures.

RESULTS

All of the results are summarized in Table I. The number of times the high and low values were obtained before and after each operation is indicated in order that a comparison of frequencies may be made in case they are of equal value. The average emptying time is recorded both in hours and in per cent of the normal, the latter to simplify comparison and to offset individual variations between different animals. The medians and modes are given in the last columns for comparison with the average. Note the relatively insignificant disagreements between the averages, the medians and the modes.

In only two cases were the average emptying times of the stomach decreased by any of the procedures. In

*From the Department of Physiology, West Virginia University, Morgantown.
Submitted August 22, 1935.

all other cases there was an apparent increase. The exceptional decreases (A-IX and B-I) were about one per cent, which is not significant. The increases in emptying times were larger and more variable in the case of gastro-enterostomy, though even here most of the increases fell within the range of error of the method, which has been calculated as 8 per cent.

DISCUSSION

The figures for the gastric emptying times in our Table do not agree with those given by some authors. The type of meal used undoubtedly influences this time. We explain our somewhat longer emptying times on the basis of the meal used. We fed an adequate diet for a dog and it was given daily in amounts sufficient to maintain a small dog. In larger animals it was necessary to give accessory feedings. We have not been concerned, in this paper, with a determination of emptying times *per se* but rather with the relative emptying times before and after given operative procedures.

These results in no way contradict the clinical results usually obtained from Rammstedt operations. In such cases the emptying time is actually shortened but it is a matter of reducing a pathologically long emptying time to a physiologically normal one, beyond which, our results indicate, it is impossible to go.

Although not repeating McCann's results (5), these experiments serve to confirm his contention that the entire pars pylorica, rather than the pyloric sphincter solely, participates in the function of food retention in the stomach. Our differences seem to show that the pyloric sphincter is of even less significance than he supposes, although it is conceivable, of course, that the function of a normal sphincter might be taken over quickly by the remaining pars pylorica.

Pannett's results (6) were obtained on cats. Leaving aside any considerations of possible species variations, it is possible that his observations may have been applicable to our results also. We made no observations on the first appearance of food in the duodenum. We limited ourselves to a determination of the time at which the stomach was completely empty. Our results did not conflict with what he admits might have been his if he had continued his observations for a longer time.

In animals with gastro-enterostomy there seems to be little difference whether the pylorus is patent or ligated. There is a suggestion that emptying may be a little more rapid if the pylorus is left patent, though individual variations between different animals make this insignificant. The large increases and individual variations after operation are undoubtedly related to the position and size of the stoma and to the particular muscle fibers of the stomach which are interrupted to make place for it. We thought that because of the normal standing position of the dog an anterior gastroenterostomy might be more efficient than a posterior one. Our one attempt was not successful, however, as

the animal after operation was not suitable for further experimentation. Possibly a series might produce enough data to decide this point.

Our results on partial denervation of the pyloric sphincter failed to confirm those of Hughson (8) but were in agreement with those of Fetter, Barron and Carlson (9), and of Meek and Herrin (10). Partial parasympathetic denervation did not remove any of the food retaining function which the pyloric sphincter may normally exert. This does not mean that the vagus does not carry motor fibers to the pyloric sphincter for this has been demonstrated repeatedly by many workers. Motor fibers in the vague were also substantiated in this same animal, in another experiment, for it was shown that a particular stimulus (anoxemia, 13) caused motor activation of the pyloric sphincter before denervation and failed to afterwards. It does seem to mean that in the normal animal motor impulses do not reach the pyloric sphincter over the vagus during normal gastric emptying which by their absence after vagus section make themselves conspicuous by a decreased emptying time of the stomach. Incidentally, it is impossible to re-duplicate the results of vagus section in these experiments by atropine as we have indicated elsewhere (13).

The criticism might be made that postoperative averages are high because of the inclusion of results obtained so soon after operation that convalescent increases were still operative. This may be answered by a comparison of the high and low values before and after operation and the number of times these occurred when they were approximately equal. In addition, two animals were studied a year after operation with values only slightly, not significantly, different from those obtained during the second week after operation (see A-VIII and A-IX, Table I.).

Another possible criticism of results in this type of experiment must be mentioned. It may be that if the pyloric sphincter is effectively replaced by an unguarded exit from the stomach that materials which are usually excluded from re-entering the stomach are regurgitated. The problem then becomes, however, simply one of definition of the term "empty." We consider that this definition is not concerned with where the material may have come from, but rather with what is *in* the stomach.

Although the weight of the data presented in this paper indicates that the pyloric sphincter itself is not of very great importance in food retention in the normal stomach, this does not necessarily indicate that it is entirely without function. It may be simply another specific example of a margin of safety.

SUMMARY

Section of the pyloric sphincter (Rammstedt operation), gastro-enterostomy or partial parasympathetic denervation of the sphincter do not decrease the emptying time of the stomachs of dogs. This would seem to indicate that the normal pyloric sphincter under the influence of the stimuli effective during normal gastric evacuation, is not of appreciable value in gastric food retention.

If the pyloric sphincter itself is of value in food retention in the stomach during normal gastric evacuation, this function is taken over very quickly by some other structure after the sphincter has been sectioned, supplemented or partially parasympathetically denervated.

Extensive Resection of the Small Intestine in the Rat with Special Reference to Anemia*

By

HOWARD L. ALT, M.D., Ph.D.
CHICAGO, ILLINOIS

THE relationship of anemia to abnormalities of the small intestines has been referred to frequently in the recent literature (1, 2). Any condition that interferes with the absorption of hemopoietic materials from the small intestine might lead to a deficiency type of anemia. Both macrocytic and hypochromic anemias have been observed in cases in which there is apparently a faulty intestinal absorption, e. g. coeliac disease (3); sprue (1, 4); chronic diarrhea (5); intestinal resection (1), stenosis (6), or anastomosis (4), and gastro-jejuno-colic fistula (7, 8). The simplest experimental method of mechanically decreasing the absorbing surface in the bowel is to remove a portion of it. The present study is concerned with the radical resection of the small intestine in the rat to determine further the effect of diminished intestinal absorption on hemopoiesis.

Although there are many reports in the literature of patients who have had more than two meters of small bowel removed (9), there are very few data on the

condition of the blood in this group. Becker (10) reported the case of a woman of 29 years who had over two meters of small intestine removed. Five months later, she developed a pernicious anemia blood picture and responded to liver therapy. Becker (10) quotes a case of Ryti's which also developed pernicious anemia after resection of over two meters of bowel. Saltzman (11) described the case of a woman who had 222 cm. of the jejunum removed. Four years after operation, she had pernicious anemia with achlorhydria and responded to liver therapy. Miller and Rhoads (12) stated that they removed all but a few centimeters of the ileum in dogs with the resultant production of a mild hypochromic anemia. Flint (13) found that dogs from which as much as 80 per cent of the jejunum and ileum was removed could live indefinitely but did not show a true recovery. At first, there was an excess secretion of fat and nitrogen in the feces. Gradually, the bowel hypertrophied to about twice its normal size and the nutritional balance was restored. No studies of the erythrocyte counts and blood hemoglobins are recorded.

EXPERIMENTAL

Extensive resection of the small bowel was performed in albino rats of the Wistar strain, by the method described by Jung and Jones (14) for gastrectomy in rats. This consists in the use of a magnesium cannula** over which the intestinal stumps are ligated. The cannula is completely absorbed in about two weeks. The average length of the jejunum and ileum in an adult rat was found to be about 100 cm., and of the duodenum, about 10 cm. In the first series of rats, about 40 cm. of intestine were removed beginning a few centimeters below the duodenal-jejunal flexure. In the second series, beginning at the same level, an average of 80 cm. of intestine were removed.

The age of the rats used in Series 1 was three to four and a half months and in Series 2, five and a half to seven months. In Series 1, 1 mg. iron and 0.025 mg. copper were added to the drinking water daily for two weeks preceding operation to insure an adequate storage of these minerals. The rats were kept singly in wire cages and received a stock diet of two-thirds whole wheat (containing 1% iodized sodium chloride) and one-third whole milk powder.

All rats were fasted for twenty-four hours preceding operation. The abdominal hair was removed with a solution of potassium sulphide, and operation was performed aseptically under ether anaesthesia. A 2 to 3 cm. incision was made in the midline and the small bowel was exposed. Wire clamps were placed 3 to 5 cm. below the duodenal-jejunal flexure and at about 40 cm. (or 80 cm.) below this

**The cannulae used were flanged and the dimensions were 9 mm. long and 2.5 mm. in internal diameter. Recently, Dr. Jung has found that a cannula 4 mm. long and 3 mm. in internal diameter is more satisfactory. The cannulae were purchased from V. Mueller and Co., Chicago.

TABLE II

Protocols on Rats Following Removal of 80 Per Cent of Jejunum and Ileum

Rat	Date	Wt. gms.	R. B. C. mill./c.mm.	Hb. gms./100 c.c.	C. I.	Remarks
312	11-2-34	193	8.1	14.0	.94	80 cm. jejunum-ileum removed.
male	11-23	218				
	12-7	153	7.3	13.6	1.02	
born	12-29	188	5.2	7.6	.86

	3-27	250	12.1	18.0	.81	
	5-9	255	10.2	17.8	.95	Skin reddish scales on back.
	5-23-35	232				Rat in fair health—sacrificed. Marked hypertrophy of bowel

level. Bull dog clamps were placed about 1 cm. inside the wire clamps on the portion of the bowel to be removed. In Series 1, the mesentery of the bowel to be excised was included in one cat gut ligature while in series 2, two ligatures were used. The segment of small intestine was then excised and the free ends of the bowel anastomed end to end by ligation with cat gut to a magnesium cannula. The peritoneum and fascia were closed with a continuous cat gut suture and the skin with interrupted silk sutures. Following the operation, the rats were given white bread soaked with milk for two weeks, following which the stock diet was resumed.

Erythrocyte counts were performed with Bureau of Standards equipment and the blood hemoglobins with the Newcomer apparatus standardized by the oxygen capacity technique. Erythrocyte counting pipets and micro-colorimeter cups were used in the determination of the hemoglobin. Hematocrit determinations were made by the method of Rosahn (15). Blood was obtained from the tail for all determinations. The average normal erythrocyte count for rats in this colony was 8,500,000 per cu. mm. and the hemoglobin, 15.5 gms. per 100 cc. These figures were used in computing the color indexes.

RESULTS OF REMOVAL OF 40 PER CENT OF THE JEJUNUM AND ILEUM

In Series 1, 14 rats were operated, of which 7 died within a period of 21 days. The causes of death in this latter group were peritonitis, hemorrhage, lung abscess, and intestinal obstruction. These are omitted from further discussion. Of the remaining seven rats (see Table I.), No. 218 died of peritonitis after five months, No. 210 was sacrificed after the same period because of multiple abdominal tumors, and No. 205 became quite sick after 8 months and was sacrificed. The cause of its illness was not determined. Rats 202, 207, 209 and 306 remained quite normal and were all sacrificed after nine months.

The preoperative weights were reached in ten to twenty-seven days (av. 21) after operation. The animals continued to gain weight, and the maximum reached was practically that of normal adult rats in this colony. The four rats that were sacrificed nine months after operation appeared normal in every respect. There was no diarrhea in any rat in this series. During the first 1 to 2 months following opera-

tion, there was a tendency for the rats to have a mild anemia which was characterized by a color index of one or less than one. At the lowest levels, the erythrocyte counts varied from 5.4 to 7.1 million per c.mm. and the hemoglobins 9.3 to 11.8 gms. per 100 cc. The rats gradually recovered from the anemia without treatment.

At autopsy, there were always adhesions about the stoma, but no stenosis occurred in this region. In three rats, the remaining small bowel was of normal size. In two rats, there was moderate hypertrophy in localized segments of the bowel and in another rat, the remaining jejunum and ileum had hypertrophied to twice the normal size throughout. In the remaining rat, the anatomy of the bowel was distorted because of peritonitis. The term hypertrophy in the protocols indicates an increase in transverse size as determined by external macroscopic examination and the degree of hypertrophy is designated by slight, moderate, or marked. A detailed anatomical description of the remaining bowel will be the subject of another report.

RESULTS OF REMOVAL OF 80 PER CENT OF THE JEJUNUM AND ILEUM

In Series 2, 12 rats were operated, of which six died within a period of 19 days. The cause of death of rats in this latter group was infection or abscess formation about the stoma with secondary peritonitis. These are omitted from further discussion. Of the remaining six animals (see Table II.), No. 318 died 4 months after enterostomy following a Caesarian section, No. 314 died after 7 months of intestinal obstruction, and No. 317 died at 8½ months of pneumonia. Three rats (312, 319, 315), whose condition became rather poor, were sacrificed at 6, 6 and 8½ months, respectively.

It is apparent that these rats required about twice the time to regain their preoperative weight as those in Series 1. The extremes were 24 to 74 days, with an average of 44 days. After this, they continued to gain to about the same maximal levels as in Series 1. The slower gain after operation might be partly explained by the fact that the rats in Series 2 were older.

After recovery from the operation, the rats appeared to be quite normal. There was no diarrhea, but the stools seemed to be somewhat larger than normal and contained undigested food particles. About five months after operation, the surviving five rats developed skin lesions. Rats 312, 314 and 319 had reddish scaly lesions on the posterior aspect of the back, while rats 315 and 317 had crusts around the neck and back of the ears. In addition, rat 315 developed marked scaling of the tail. From this time on, all rats began to lose weight, and the skin lesions became progressively worse. Because of their downward course, the rats were sacrificed within the periods noted above. It seems questionable whether any would have survived longer than nine months. Rat 315, sacrificed at 8½ months, had severe skin lesions and showed loss of weight and marked loss of activity.

The *blood picture* varied somewhat in different rats in Series 2. Rats 312 and 314 developed a rather marked anemia which continued for a period of about eight to ten weeks following operation. At the lowest levels, the erythrocyte counts were 5.2 and 3.8 million per c.mm., and the hemoglobins 7.6 and 6.2 gms. per 100 cc., respectively. From color index and volume index determinations, the anemia in general was found to be of the hypochromic microcytic type. The blood pictures gradually improved without treatment. The remaining four rats had a less marked anemia which was similar in degree and course to that observed in Series 1. The period of decline after five months studied in several rats was not accompanied by any remarkable changes in the blood picture.

Because of the fact that Ivy, Morgan and Farrell (16) observed anemia in gastrectomized dogs during pregnancy, the effect of pregnancy was studied in these rats. About 2½ months after the bowel operations, the three males in series 2 were placed individually with females in the same series. Rat 315 never became pregnant although several normal males were used for mating. Rat 317 gave birth to a litter of eight young 4 weeks after being placed with the male. Five of these were eaten by the mother within two days, and the remainder died shortly thereafter. The blood studies in the mother were normal six days before delivery, and on the day preceding birth the erythrocyte count and hemoglobin were depressed to within the range occurring during normal pregnancy. The mother's condition seemed to be quite normal before and after the pregnancy. Rat 318, four weeks after being with the male, had a bloody vaginal discharge, was breathing rapidly and appeared quite sick. The next day, Caesarean section was performed and five full term fetuses were removed. Two of the young did not breathe, while three breathed for about fifteen minutes and then expired. The mother died the next day and at autopsy two more fetuses that were not seen at operation, were found in the opposite uterus. Blood studies three days before Caesarean section showed depression of the erythrocyte count and hemoglobin only slightly lower than the average values seen in normal pregnancy. It is thus shown that a pathologic anemia did not occur in rats with extensive resection of the small bowel when they became pregnant.

The remaining jejunum and ileum in all rats in Series 2 showed varying degrees of hypertrophy at autopsy. In all but one case, there was also hypertrophy in the duodenum. The small intestine varied from twice to four times its normal size. In some rats, there was only hypertrophy of portions of the intestines, while in others the enlargement was general throughout. As was to be expected, the hypertrophy following resection of 80 per cent of bowel was more extensive and marked than after the removal of only half as much bowel.

COMMENT

These studies show that the rat can survive when as much as 80 per cent of the jejunum and ileum is removed. Following a period of loss of weight and mild anemia, the animal improves and seems to approach a normal condition. This period of improvement is probably related to a compensatory mechanism in the remaining gut. When 40 per cent of the jejunum and ileum was removed, rats kept under observation for 9 months continued to be normal in every respect. However, when 80 per cent was removed, this was not the case. After a period of about 5 months, the rats developed skin lesions and began to lose weight. They all ran a down hill course and from this small series, it appears that they could not survive for

longer than 8 to 9 months following such an operation. The limits of safety in the removal of the small intestine from rats are thus indicated by these experiments.

The anemia which occurred during a period of one to two months following operation varied from a normochromic to a hypochromic type. This could be related to various factors such as hemorrhage (from operation), sepsis and iron deficiency from diminished absorption. The latter was probably the principle factor, especially in the production of the more severe anemia that occurred in two rats after radical enterectomy. The chronicity of the anemia and the slowness with which it improved is in favor of an iron deficiency caused by a decreased absorbing area in the small intestine.

At no time was a significant macrocytic anemia observed in these rats as shown by color and volume index determinations. If the physiology of hemopoiesis in the rat is similar to that in man, these experiments indicate that the anti-pernicious anemia principle was absorbed to a sufficient degree in the enterectomized rats to prevent the occurrence of a macrocytic anemia.

SUMMARY

1. In two series of rats, 40 per cent (Series 1) and 80 per cent (Series 2) of the jejunum and ileum were removed, respectively.

2. After recovery from the operation, rats in Series 1 remained normal over a nine month period of observation. Rats in Series 2 developed skin lesions after five months, began losing weight, and were sacrificed or died because of their declining condition within 8½ months after operation.

3. All rats developed a mild normochromic to hypochromic anemia following enterectomy while two rats in Series 2 developed rather marked hypochromic anemias. The blood picture usually recovered spontaneously within 6 to 10 weeks after operation.

4. Varying degrees of hypertrophy occurred in the remaining small intestines in all rats in Series 2. It occurred in only half the rats in Series 1 and was less marked.

The author wishes to express his appreciation to Dr. F. T. Jung for his assistance in the development of the operative technique.

Studies on Auto-Digestion

VI. The Digestion of Living Tissues in Stomach Juice (Claude Bernard's Experiment)*†

By

M. H. MASKIN, M.D.
R. CALLAHAN
and
H. NECHELES, M.D., Ph.D.
CHICAGO, ILLINOIS

THE physiologic mechanism of the resistance offered by the stomach and the proximal intestine to digestion by their respective proteolytic ferments still remains unexplained. Some seventy-five years ago, Claude Bernard (1) repudiated John Hunter's (2) "living principle"‡ by demonstrating effectively that living tissue, as such, displayed no immunity to digestion. The immersion of living eels or frogs into the gastric juice of a dog resulted invariably in their digestion. Somewhat later, in 1863, Pavy (3) commented: "I have found that the tip of a living rabbit's ear has similarly yielded to the influence of the digestive menstrum." Subsequently observers have noted the fat necrosis resulting from acute pancreatitis as well as the severe digestion of the abdominal wall, which may appear about an inadequately constructed Pavlov pouch or gastrostomy.

In contrast to these experiments and observations, it is now generally conceded that organ or tissue implants in the stomach (4, 5, 6, 7) or duodenum (8) are thoroughly capable of withstanding the digestive milieu, providing their blood supply is adequate. Similarly negative was Ewald's (9) observation of no defection in the shaved paw of a living dog maintained for six hours in a mixture of glycerine gastric extract and HCl at body temperature.

Notably, three theories have been advanced to explain the resistance of the stomach to autodigestion. Bernard (1) ascribed the protection to the lining cells and their mucoid secretion. Since healing normally occurs rapidly if a segment of mucosa is avulsed, this assumption is now invalidated. Weinland (10) ascribed the preservation of the stomach to specific antiferments, which were also present in parasitic intestinal worms. However, previous work (11, 12, 13) in the present series of papers concluded that the existence of a specific anti-trypsin was doubtful, and similarly the possible presence of a specific anti-pepsin is questionable (14). Finally Pavy (3) "refers the immunity observed to the circulation within the walls of the organ of an alkaline current of blood." And he continues: "If the circulation through its neutralizing power protects the stomach why does it not protect the ear and the frog? The result is involved in a question of degree of power between two opposing influences and because through degree of vascularity, the neutralizing power of the circulation is sufficient to hold in check the solvent action of the gastric juice in the case of the stomach, it does not follow that it should similarly be sufficient to do so in the case of the frog's legs and the rabbit's ear. With the frog it may be fairly taken that the amount of blood possessed by the animal would be totally inadequate to furnish the required means of resistance to the influence of the acidity of a dog's gastric juice. With the rabbit's ear the vascularity is so much less than the walls of the stomach that there is nothing incomprehensible in the fact of the one yielding to and the other resisting the attack. In support of the position that has been taken, it can be shown by experiment that even with the stomach itself, by increasing the acidity of its contents beyond a certain point, its circulation is no longer adequate to enable it to resist digestion."

This theory has received some confirmation. Dragstedt and Vaughn (4) have repeated Bernard's (1) experiment and successfully digested living frogs in the gastric juice of man, dog and frog. They stress the importance of the concentration of HCl in the digestive medium, observing that the greater the concentration of acid, the greater the intensity of digestion; and that, moreover, blood vessels exhibited a greater relative resistance to peptic hydrolysis. Necheles and Fernando (1926) in unpublished experiments, made similar observations. More recently Dragstedt has reported that chronic progressive ulcers developed in experimentally isolated stomachs or Pavlov pouches (15) and that organs implanted into Pavlov pouches, with their higher unneutralized acidity are subjected to digestion (16). The presumptive importance of acidity for auto-digestion is further attested by the failure of human peptic ulcer to develop in the presence of complete anacidity (17), the not infrequent appearance of jejunal ulcers following gastro-enterostomies, the occasional development of ulcers in the ileum contiguous to a Meckel's diverticulum containing heterotopic gastric mucosa (18, 19), the diminished gastric mucus content of ulcer patients (20, 21) and the ulcer-

‡"Animals, or parts of animals, possessed of the living principle, when taken into the stomach, are not the least affected by the powers of that viscus, so long as the animal principle remains; thence it is that we find animals of various kinds living in the stomach, or even hatched and bred there; but the moment that any of those lose the living principle, they become subject to the digestive powers of the stomach. If it were possible for a man's hand, for example, to be introduced into the stomach of a living animal, and kept there for some considerable time, it would be found, that the dissolvent powers of the stomach could have no effect upon it; but if the same hand were separated from the body, and introduced into the same stomach, we should then find that the stomach would immediately act upon it." (2).

ation yielded by the Mann-Williamson operation (22).*

Unfortunately for this theory, peptic ulcer in man may co-incide with an exceedingly low, if not negligible, acidity; and apparently may heal in the midst of high acid concentrations.

A further analysis of the problem of auto-digestion seemed warranted, and this paper represents such an attempt.

PROCEDURE

The common edible frog (Rana Esculenta) and the American bullfrog (Rana Catesbiana) were employed for this work. The digestive medium was a freshly prepared 2% solution of pepsin (Wilson & Co. 1:10,000)† in N/10 HCl.

The frogs were either pithed or narcotized with ether or urethane (2 cc. of a 10% solution injected into the dorsal lymph sac), then attached to a frog board, and the legs suspended in the artificial gastric juice contained in a beaker which was immersed in a glass constant temperature bath. In this manner, perfect visibility of the progress of digestion could be guaranteed. Unless otherwise specified, all experiments were performd at 38° C.

In one series of experiments, the abdominal aorta and the abdominal vein were cannulated and the digesting legs perfused with Ringer's solution [NaCl 0.65%, KCl 0.014%, $CaCl_2$ 0.012%, $NaHCO_3$ 0.02% (Clark, 23)]. The venous outflow was collected in a separate beaker in order to avoid dilution of the digestive fluid.

The bullfrogs were used mainly for ph determinations during the process of digestion. A modification of the non-buffer colorimetric micro-method of Hastings (24) was utilized, 2 specimens of blood, 1/10 cc. each, being collected from either the aortic arch or the abdominal vein both before and after digestion of the legs.

Throughout the entire work, comparative experiments and controls were done on the same day, using the same lot of frogs and the same sample of artificial gastric juice. The peptic activity of the digestive mixture decreased somewhat from day to day even when stored at cold temperatures. In the following tables, the serial letter accompanying the number of the experiment identifies the several tests performed under identical conditions.

Degree of digestion is expressed as definite or severe. The former denotes visible defection of the skin or superficial hemorrhage, the latter indicates corrosion of skin and musculature.

Only those experiments are reported in which cardiac activity remained unimpaired at the conclusion of the test.

RESULTS

Notwithstanding that cardiac activity was more vigorous in the etherized than in the pithed frogs, ether definitely increased the rate of digestion.

One foot of a frog was exposed to digestion; and as control, both legs of another animal were immersed in gastric juice. Pithing or anesthesia with ether or urethane were variously employed. In the four groups of pithed frogs, digestion occurred definitely sooner when a larger surface was available for proteolytic action. Similarly the urethanized frogs, in whom, as in the etherized frogs, the heart beat seemed vigorous, the rate of digestion appeared as a direct function of the exposed surface area. Contrarily, definite digestion appeared in the etherized frogs at about the same time, irrespective of the surface area exposed to digestion.

Throughout these experiments, the artificial digestion mixture was maintained at a temperature of 38 degrees C. in the constant temperature bath. The objection may be proffered that the immersion of both legs in the warm digestive medium raised the body temperature of the frog, a factor which is undoubtedly neglible if only one foot is inserted; and that the increased body temperature in the former instance may accelerate digestion. This criticism was answered by experiments 21 and 22 (Table II), which were performed at room temperature, and which entirely repeated the results obtained at the higher temperature.

Section of the sciatic nerve of the dog or cat evokes an acute acceleration of the blood flow through the extremity, an old observation recently reconfirmed by the thermo-stromuhr (25). Inferentially this should also be true for the frog. Accordingly, in etherized frogs, one leg was denervated through a small slit in the upper thigh, and then both legs were submerged to the knee in gastric juice. In all but the last test (7b),

Test 21 and 22 were done at room temperature (24° C.).

*It is to be recognized that observations are available which show that true, chronic peptic ulcer can develop in the presence of anacidity. Similarly, gastrojejunal ulcer has been reported in humans whose stomachs were acid free. *Editor.*

†We acknowledge our indebtedness to Dr. D. Klein of the Wilson Laboratories for his contribution of pepsin.

the denervated leg was digested more rapidly than the normal control.

In this same group belong another series of experiments, which have not been tabulated. Ergotamine tartrate (½-1 mg.) was injected into frogs in an effort to paralyze the sympathetic nerve supply and thereby prevent vaso-constriction in the digesting legs. The results, however, were inconstant.

××No severe digestion after 20 minutes.
+No digestion after 25 minutes
Ether anesthesia. In 1a the left, in the rest of the experiments the right sciatic was cut.

Dragstedt and Vaughn (4) reported that a higher concentration of HCl in gastric juice accelerated digestion of living frog legs. Since such procedure introduced a somewhat unphysiologic element, a different approach was attempted in the present work. In this series of experiments, one leg of a frog was dipped in gastric juice and the other exposed to air, Ringer's solution, alkali (isotonic) or N/10 HCl.

It will be observed that HCl produced the most rapid digestion of the opposite leg immersed in gastric juice and alkali the slowest digestion, the experiments in air and Ringer's solution occupying an intermediary position.

With the exception of experiments 6c and 7c, the perfused legs were digested slower than the legs of control pithed frogs.

The remainder of the experiments in this group is devoted to a study of the comparative influence of perfusion with Ringer's solution with and without bicarbonate. The absence of bicarbonate tended to hasten digestion.

Experiments on Bullfrogs. The rate of digestion of bullfrog legs did not vary significantly from that observed in the small frogs.

In the course of digestion, a number of pH determinations were made upon blood taken from the aorta and abdominal vein, but the results were inconclusive. A drop of pH from 7.35 to 7.30 was observed in one blood specimen taken from the abdominal vein when digestion of the legs had set in. Similarly, a drop from 7.4 to 7.35 was noted in the blood of another animal. However, in other tests, no change in pH was observed, although severe digestion occurred.

In order to test the protective influence against digestion of the skin mucus of frogs, pilocarpine hydrochloride (1-4 mgs.) was injected into the lymph sac of frogs, and their legs submerged in gastric juice. Control frogs were simultaneously exposed to digestion. In only one frog (rana esculenta) did a visibly increased secretion of mucus develop on the skin in response to the pilocarpine, and in this frog digestion was considerably delayed. In other frogs, no significant difference could be detected between control and pilocarpinized animals. Likewise, injection of calcium gluconate did not alter the digestion time.

DISCUSSION

The data presented above can be conveniently grouped into two major categories. The first group includes those experiments which may possibly express the effect of local changes upon the rate of digestion. The second rubric comprises those experiments providing some insight into the systemic response to digestion of a living anesthetised frog.

Apparently ether exercises a deleterious action on the tissues of the frog, rendering them more susceptible to digestion. Although the circulation is certainly better in the etherized than in the pithed frogs, the former are the more rapidly digested. Significantly, the frogs anesthetized with urethane, whose circulation was entirely comparable with that of the frogs narcotized with ether, manifested a slower rate of digestion than the etherized frogs. Thus the conclusion seems justified that ether, in some way, peculiarly predisposes frog legs to digestion.

Further, it is quite as difficult to explain the more rapid digestion of a denervated leg. Actually one might expect the converse, that section of the sciatic nerve, which probably increases the blood supply to the leg of the frog, would increase the resistance of the extremity to digestion. It may, of course, be possible

TABLE IV

Effect Upon the Rate of Digestion of One Leg Immersed in Gastric Juice When the Other Leg is Simultaneously Exposed to Air, Ringer's Solution, Alkali, or Acid

that this interpretation is wrong, and that instead acute stasis results from denervation.

Perhaps the explanation for the rapid digestion induced by ether or denervation will be discovered ultimately in an increased permeability of the tissues to the digestive milieu.

Evidently the digestion of living frog legs is not merely a local phenomenon of the acid destroying the cells, which, when dead, are readily digestible. Instead, the rate of digestion is distinctly related to the surface area exposed to the gastric juice (Table II). The greater the available surface, the sooner the first signs of digestion appear. It is possible, although not probable, that the blood may contain some protective substances, whose rate of exhaustion is dependent upon the surface area immersed in the digestive medium. More likely as explanation for this phenomenon is the possibility that, although no significant change in blood pH occurs with digestion, the alkali reserve is none-the-less diminished considerably. The experiments listed in Table IV tend to substantiate this interpretation, for the immersion of one leg in isotonic alkali solution delayed digestion of the opposite extremity. The slower digestion in the perfusion experiments and the suggestive evidence contained there that bicarbonate may modify the digestion rate is also partly confirmatory. However, a number of tests in which alkali or acid was injected into the lymph sac and digestion time of the legs determined yielded inconstant results.

Two possibilities are available to account for the loss of base which may occur in the process of digestion. *Acid may be absorbed, uniting with the blood* base to form neutral salts. Or again, the gastric juice may alter the permeability of the frog's skin, which normally resists the passage of ions to the exterior, and in this manner permit an escape of base. Since calcium injections did not increase the frog's resistance to digestion, the possible loss of this important ion as a factor in digestion is ruled out.

SUMMARY

Legs of frogs anesthetised with ether are digested more rapidly by stomach juice than those of pithed frogs, or of frogs anesthetised with urethane.

Legs of frogs in whom the sciatic nerve is cut are digested more rapidly than innervated legs.

The larger the surface area of the frog's legs immersed in gastric juice, the sooner will appear the first signs of digestion.

It is concluded that digestion in this experiment is not due merely to a local process, but possibly results from alkali depletion of the blood.

SECTION III—*Nutrition*

A Survey of Four Hundred Ninety Diabetic Admissions to General Hospitals

By

LEMUEL C. McGEE, Ph.D., M.D.*
ELKINS, W. VA.

THAT diabetes and its associated complications continue to be a significant cause of physical incapacity and death, is fairly common knowledge. That this should be true in light of the present knowledge of the control of the disease has led to the author's study. We wished to observe just what the status of the diabetic patient might be in a community where the general hospitals are well equipped but have no specific diabetic service, and where the general practitioners care for more of the diabetic populace than internists who would like to emphasize diabetes.

From 1929 to 1934, inclusive, there were 490 admissions of diabetic patients to four general hospitals in Dallas, Texas. When 53 re-admissions are subtracted there were, for that period, a total of 437 patients. Of the admissions there were 223 males, or 45.5 per cent, and 267 females, or 54.4 per cent. The age distribution by decades is as follows:

TABLE I
Age Distribution by Decades

Decades	1st	2nd	3rd	4th	5th	6th	7th	8th	9th
Males	7	17	30	30	35	44	38	20	1
Females	6	21	23	34	41	60	53	20	0
Total	13	38	53	64	76	104	91	40	1
Per cent	2.7	8.0	11	13.4	15.8	21.7	19.0	8.4	

(The above includes 480 patients. Ages of 10 patients were not recorded).

It is to be noted that there is a slight preponderance of males in the third decade group and a preponderance of females in the sixth and seventh decades (Fig. 1). The model class for both sexes is the sixth decade. Murray-Lyon (1), in an analysis of 1700 cases, likewise found that relatively more males developed diabetes before the age of 40 years. (37.9 per cent of men and only 19.9 per cent of women developed the disease before this age). Authors seem fairly well agreed that women are more susceptible to diabetes than men. Murray-Lyon found 64.5 per cent of his group to be women.

In the present series the date of onset of symptoms could be fairly well determined in 347 patients. There were but 83 patients (24 per cent) of this group who entered the hospital for the first time within 5½ months of the beginning of their illness and there were 86 patients (25 per cent) who had symptoms of diabetes for 5½ years or longer before their first hospital admission. The average duration of symptoms before the first admission was 42 months (3½ years). The average loss of weight in the patients before admission was 31 pounds.

There were 81 deaths of the following causes:

TABLE II
Diabetic Deaths

Cause of death	Number of deaths	Per cent
Coma	31	38.3
Cardiovascular-renal (uremia-gangrene)	25	30.9
Septicemia	12	14.8
Pneumonia	8	9.9
Skull fracture	2	2.4
Strangulated hernia, carcinoma and undiagnosed	1 each	

COMA

There were 62 patients admitted in varying stages of coma with a mortality of exactly 50 per cent. In the group of 31 deaths from coma there were 22 patients who died in less than 48 hours after admission to the hospital. This group of moribund patients actually averaged but 17 hours in the hospital before death. The remaining nine patients from the group dying in coma were in the hospital from 53 hours to 5 days. Thirteen of the group were males and eighteen were females.

Flynn (2), in 43 diabetic deaths, (Peter Bent Brigham Hospital, 1923-1933) found only 5 per cent due to coma; 49 per cent, cardiovascular-renal; 28 per cent, sepsis; 7 per cent, pulmonary tuberculosis; and 11 per cent, unusual complications. The Metropolitan Life statistics show coma as the cause of death in 37 per cent of the total fatal cases of diabetes for 1930 (3). In New York City for the same year, Bolduan (4) re-

*Formerly instructor in Medicine, Baylor University, College of Medicine
Submitted December 20, 1935.

ported 23 per cent of diabetic deaths as due to coma. In the New England Deaconess Hospital (5) from May, 1923, to October, 1934, coma deaths constituted but 11.4 per cent of the total deaths. Of 276 coma admissions there were 35 deaths (12.7 per cent).

It seems obvious that carelessness and ignorance on the part of the diabetic patients, negligence and incompetence on the part of many physicians treating diabetes, and certain, as yet, uncontrollable factors in diabetic coma (notably shock and hyperpyrexia) (6) are responsible for the high mortality in this group. The great majority of diabetic patients scattered over the continent are not benefiting by the accumulated medical knowledge of the prevention and treatment of diabetic acidosis.

GANGRENE

In the present series seventy-three (15 per cent) of the patients admitted with diabetes had gangrene as a complication. The average age for gangrene in the charity hospital group (42 patients) was 52.2 years; the average for gangrene in the private hospital group (31 patients) was 59 years; the average for the total, 55.3 years. In the total group there was record of an amputation in 16 patients with 7 deaths soon after amputation. In the total group of 73 there were 21 deaths, a hospital mortality of 29 per cent in patients with gangrene.

In those patients with gangrene where the duration of symptoms was recorded, an average of 7½ years elapsed between onset of the illness and admission to a hospital. There were 37 males and 36 females with gangrene of one or both lower extremities. The information available in the series does not warrant separation of the group into "arteriosclerotic gangrene" and "diabetic gangrene" by the criteria of Kramer (7). Kramer reviewed the incidence of gangrene from twelve hospital series and found it to vary from 3.2 per cent at the University Hospital, Michigan, to 18.0 per cent in the Charity Hospital, New Orleans, in the period 1921-1926. The average for the group was 6.28 per cent. Kramer's 58 cases constituted but 5.75 per cent of his own group of diabetic patients. Strauss (8), in the Jewish Hospital in Berlin, found gangrene of the extremities in 7 per cent of men and 5 per cent of women. Vale (9) found gangrene in 6.9 per cent of diabetic admissions. Eliason and Wright (10) found that 104 (16 per cent) of 652 patients had gangrene and had an immediate operative mortality of but 3 per cent though there was a follow-up mortality of 61.1 per cent in twelve months. Dillon and Hitzrot (11) had 29 (4 per cent) patients with gangrene in 725 diabetic admissions. Murphy and Moxon (12) found 72 (8.7 per cent) patients with gangrene in the Milwaukee County series (from 1922-1930) of 827 patients. Sevringhaus (13) had 50 (10 per cent) cases of gangrene in 500 patients.

In the Dallas series it is found that 27 patients (34 per cent) of the group with gangrene are less than 51 years of age. This gives an average age for gangrene in hospital admissions comparable to the average age in an era before the use of insulin (10). In fact, only a minority of the group of patients with gangrene gave a history of the use of insulin before appearing at the hospital.

The 25 patients dying a cardiovascular-renal death, including uremia and gangrene, were all over forty years of age, fifteen of them being in the seventh and eighth decades. The average age for the group was slightly above sixty years.

OTHER COMPLICATIONS

Of the complications presented by the patients in the present series, arteriosclerosis, as would be expected, leads. (Table III). Its mention occurs in 181

TABLE III

Complications of Diabetes Mellitus

Complications	Number of patients	Per cent
Arteriosclerosis	181	37
Gangrene	73	15
Coma (including semi- or pre-coma)	62	13
Furuncle, abscess or carbuncle	48	10
"Diabetic neuritis"	40	8.2
Syphilis	25	5
Cataract	17	3.5
Tuberculosis	10	2.0
Psychosis	8	1.6

(37 per cent) of the clinical records and we may presume that the figures should be even higher. Its significance is appreciated by a reference to the causes of death in any group of diabetic patients.

There were 40 patients (8.2 per cent) with symptoms of diabetic neuritis. This, again, is a finding not carefully sought for in the hospital histories. Murray-Lyon (1) found neuritis in 24.6 per cent of his patients and Sevringhaus (13) found it present 36 per cent of the time.

A positive Wassermann occurred in 25 (5 per cent) patients, most of them having latent syphilis, i. e., without clinical evidence of the disease. Lemann (14), in 1929, found 3.6 per cent diabetic patients with syphilis and concluded that there was little ground for an assumption of a causal relationship between the venereal infection and the failure of the carbohydrate metabolism. Brandau (15) reported a case of the combined disease in 1930 where anti-syphilitic treatment brought an improvement in the carbohydrate tolerance. He felt that such a relationship must be rare.

Root (16) has treated thoroughly of the relationship of tuberculosis to diabetes. He found 101 patients (6.7 per cent) in a group of 1503 fatal cases of diabetes to have tuberculosis. The Dallas series has a record of pulmonary tuberculosis in ten patients (2 per cent). Fitz (17) found 35 cases (2.3 per cent) of tuberculosis among 1529 diabetic patients. Lyon (18)

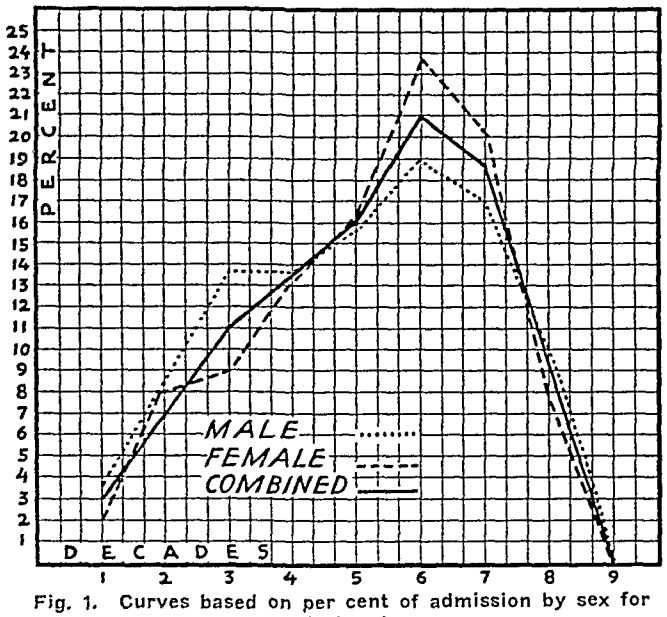

Fig. 1. Curves based on per cent of admission by sex for each decade.

reported 11 deaths (7.3 per cent) from tuberculosis in 150 diabetic fatalities in England. Among 6000 of Joslin's (19) patients there were 127 patients (2.1 per cent) with tuberculosis. Murphy and Moxon (12) had 40 cases (4.83 per cent) in the analysis of records of 827 diabetic patients. Flynn (2) found tuberculosis one of the four common causes of death in diabetes mellitus. He reported that in a group of 43 hospital diabetic deaths, with autopsy, in the past eleven years, tuberculosis caused the death in 3 patients (7 per cent). In contrast, Sevringhaus (13) considered tuberculosis infrequent, having found but 3 deaths from that cause in 500 patients.

HEREDITY

Forty-five patients gave a family history (implying only parents, brothers and sisters) of diabetes, an incidence of slightly more than 10 per cent (discounting re-admissions). This figure would undoubtedly be higher if the family histories had been more carefully recorded and had included information concerning grand-parents, siblings, cousins, etc. Sevringhaus (13) obtained a family history of diabetes in 102 patients (20.4 per cent) of his group. Strauss (8) noted hereditary influences in 20.6 per cent of the women and 29.7 per cent of the men in the Jewish Hospital in Berlin. Cammidge (20), in 1934, published the high incidence of 396 (39.6 per cent) in 1000 diabetic patients with a familial history of the disease. There were 50 patients (10 per cent) in a control group of 500 non-diabetic histories with diabetes in some member of the family. Wright (21) carefully reviewed the topic and reported the findings of twenty-one authors between 1878 and 1928. The family incidence varied from 5.3 per cent to 43 per cent with an average of 20.5 per cent. Maddox and Scott (22) emphasized the need for care in recording the family history and in considering all blood relatives. They found that the family incidence can be determined in one-third (34 per cent) of the patients with diabetes mellitus and in 10.8 per cent of non-diabetic patients.

RACE

Of the diabetic admissions, there were 18 colored males and 26 colored females (an incidence for the negro race of 9 per cent). This group had a relatively higher proportion of complications, especially gangrene, than was observed in the white diabetic patients. Otherwise we find, as did Leopold (23), that diabetes in negroes differs in no notable character from the disease in the white race. Leopold found that the negroes formed 28.8 per cent of the new admissions to the Diabetic Clinic in Baltimore. Syphilis seemed not to play an etiologic rôle in the colored race.

PREVIOUS TREATMENT

It was observed that but one-third of the patients in the present series had made the slightest effort to control their disease before admission to a hospital, in spite of the fact that the average duration of diabetic symptoms had been 3½ years. Eisenbud (24) has been impressed with the small fraction of diabetic patients receiving proper care. In 195 patients with diabetes admitted to Harlem Hospital from 1930 to 1932, he found that only 6 had received proper care prior to admission.

SUMMARY AND CONCLUSIONS

1. A survey of 490 diabetic admissions to four general hospitals in Dallas, Texas, shows the disease well distributed in all decades of life, with the greatest number of admissions in the sixth decade and with slightly more females (54.5 per cent) affected than males. Before the age of forty, diabetes occurred more frequently in males.

2. In considering the duration of symptoms before the first hospital admission the median was found to be 42 months (3½ years) and the quartiles, 5½ months and 66 months (5½ years) respectively.

3. Of the total admissions there were 81 deaths (16.6 per cent) in the hospital. Coma, the availability of insulin notwithstanding, was the chief cause of death (38.3 per cent of the fatal cases) in the period 1928 to 1934. Cardiovascular-renal complications led to death in 30.9 per cent and septicemia in 14.8 per cent.

4. One-half of a total of 62 coma patients died in coma. Twenty-two of these were admitted as moribund patients and died within a few hours. Of 39 patients less than 40 years of age with coma, 16 (41 per cent) did not survive.

5. Seventy-three (15 per cent) of the admissions had gangrene of one or more of the extremities and at the average age of 55 years.

6. No attempt has been made to analyze the factors responsible for the continued seriousness of diabetes mellitus, a controllable disease, as a social and medical responsibility. No separate diabetic service is maintained in any of the four hospitals furnishing this series. It is felt that the facilities offered for the

treatment in this group are on a par with a cross-section of the facilities in the nation at large. In an attempt to obtain better management of diabetes in this locality, the author, in 1934, began an out-patient clinic in co-operation with the City-County Hospital to afford frequent consultation and careful education of indigent diabetic patients both prior to and after hospital admissions. Some means must be found to lessen the disparity between the available scientific knowledge of the disease and the present application of that knowledge to the vast majority of patients.

Acknowledgement

The author wishes to acknowledge the assistance, in the collation of material in this paper, of Drs. G. E. Penny, M. K. Leggett and P. R. Rodriguez of the Class of 1935, Baylor University College of Medicine, and the kind co-operation of the various hospitals of Dallas, Texas.

Radiological Demonstration of an Allergic Reaction in the Mucosa and Musculature of the Colon

By

L. P. GAY, A.B., M.D., F.A.C.P.
ST. LOUIS, MISSOURI

DISTURBANCE in the muscular tone of the colon after the ingestion of a specific symptom producing food was first described by Eyermann (1). He was able to reproduce the original pain by the purposeful inclusion of wheat in a wheat sensitive patient's diet, and during this experiment, by palpation of the colon at frequent intervals, observed an increasing spasticity and tenderness throughout its entire length. A film of a barium enema taken during a period when pain was not present showed a normal haustration with a tendency to hypotonicity in the ascending portion of the colon. A later film was made while there was subjective pain present due to the feeding of wheat and showed a "disharmonic colon, hypotonic in the caecum and ascending portion and hypertonic in the transverse and pelvic portions. The haustra are small, distinct and well separated." Symptoms were relieved at this time by the administration of adrenalin. Rowe (2) was able to demonstrate gastric retention arising from pylorospasm due to food allergy and to produce hypermotility and colonic spasticity after the purposeful feeding of known allergene in patients whose previous radiological studies while on compatible diets were distinctly normal. Andresen (3) has recently called attention to the marked variation in radiographic findings at interval observations which he attributes to muscle spasm and to edema of the gastric and intestinal mucosa, due to allergic reactions. Morris (4) demonstrated edema in a piece of gastric mucosa recovered during the process of lavage in a patient with generalized angio-edema and with

Submitted January 6, 1936.

Fig. 1. Taken during the attack of pain showing incomplete canalization, marked spasticity of the colon, intolerance of the splenic flexure of the colon to barium with distinct visualization of this portion of the colon due to thickening from edema and the shadowy outlines of the partially filled haustral forms of the mid portion of the transverse colon from the same cause. Note difference between the mucosal edema and gas in other portions of the film.

gastro-intestinal symptoms. Christian (5) recounts the experience of a patient with obstructive symptoms who had a sausage like shadow in an upper loop of the ilium which disappeared spontaneously. As the patient had previously developed urticaria and purpura, and as both of these conditions are now known to be allergic possibilities, it is quite likely that this was a demonstration of edema of the intestinal mucosa. Radiographic demonstration of edema of the intestinal tract is difficult as the condition tends to be transitory and frequently the patient is too acutely ill to be subjected to manipulation. In the following case edema and spasm of the colon was visualized quite by accident.

Mr C B., aged forty, was seen in consultation on January 9, 1934. He had been perfectly well until about ten a.m. on the preceding day when he began to have an agonizing pain in the lower abdomen which increased in severity and produced a desire to defacate. He had a normal bowel movement but no relief from pain. By midafternoon the pain had increased in severity and he called to see his physician who gave him some powders to take. The medication had no effect other than to produce nausea. Because of nausea no food was taken at the usual dinner time and at eight o'clock he vomited some mucus. As the pain continued he called his physician who told him that he had a temperature of 102° and gave him a hypodermic injection to ease the pain. He was able to sleep a short while but was awakened in the early morning by pain. Later in the morning he had a temperature of 101°, and as the leukocyte count had been found to be 17,000, his physician advised hospitalization and an exploratory operation. The patient consented to go to a hospital but requested a consultation before he was willing to submit to an operation. At five p.m. when seen by me the patient was evidently in great pain but he did not look toxic. He described his pain as constant with acute exacerbations starting in the umbilical region, gradually increasing in severity to a peak, then being referred down the left side of the abdomen and slowly being partially relieved. There had been no bowel movement since the preceding day but small amounts of flatus had been passed. The abdomen was greatly distended throughout and perfectly rigid There was marked tenderness in the right and left lower quadrants. Deep palpation in either region reproduced the cyclic pain. The pelvic colon was palpable, spastic and exquisitely tender. By following the course of the descending colon up the left side of the abdomen to the splenic flexure and exerting pressure it was found that the cyclic pain could be reproduced. The transverse colon could not be palpated owing to muscle rigidity. It was noted that the patient had a very marked tache cerebrale. His temperature was 100.4, pulse 96 and the leukocyte count was 12,500 In order to rule out an intestinal obstruction an open roentgen film of his abdomen was taken and found to be negative except for much gas. To eliminate diverticulitis of the sigmoid a barium enema was suggested and the colon as far as the distal half of the transverse colon was slowly and painfully canalized. The film of the opaque enema showed a very spastic colon but no other abnormalities that were recognized at the time. On close re-questioning the patient from the standpoint of a possible food sensitization which

Fig. 2. Barium enema taken four weeks after the attack of pain showing complete canalization of the colon

was suggested by the markedly hyperactive skin, it then developed that there had been a very severe attack of urticaria six years previously from bananas, and that nausea, vomiting and diarrhea had occurred in childhood and in early adult life whenever he ate pork. After abstaining from pork for fifteen or twenty years, he had eaten a large quantity of fresh pork sausage on the evening preceding the attack. There was a strongly positive allergic history in two sisters but none in any other members of his family. Adrenalin as a method of specific therapy was objected to by the family physician so morphine gr.¼ and atropine sulphate gr.1/100 was given. This was considered to be a safe procedure as the temperature and leukocyte count were lower than the earlier determinations and also because it was felt that the condition was of an allergic nature. The patient was seen the following morning and though greatly improved still had the recurring cycles of pain in a less degree. As rigidity had disappeared the entire colon could be palpated and was tender throughout its course. A proctoscopic examination was made. The mucosa of the rectum and pelvic colon was a shiny red and coated with a glistening mucosa. There were no ulcerations or points of hemorrhage. The stained smears of the mucus contained large numbers of eosinophiles. Adrenalin was again advised, it was given and relief from pain was experienced as a result. The patient made an uneventful recovery. Since that time he has experienced a similar but much less severe attack from eating baked beans cooked with pork.

Though it was established later by test, by passive transfer and by trial diet that this condition was due to a food sensitization, and it was recognized that the marked spasticity and tenderness of the colon was an allergic manifestation, the edema of the mucosa was not recognized as such until long after this case had been included in a report on "The Acute Allergic Abdomen" (6).

By comparing the radiograph shown in Figure 1, which was taken during the attack of acute pain, with the one taken four weeks later, it will be seen that there is a shadowy outline of the bowel in the more distal portion of the transverse colon as it approaches the splenic flexure and that the barium filled haustral forms are outlined in a similar fashion. These shadows are interpreted as being edema of the mucosa of the colon and it will be seen that they are quite distinct in appearance from the shadows of colonic and intestinal gas which can be seen in other portions of the film. Furthermore no such shadows are to be observed in the radiograph which was taken later.

The clinical picture as presented here was considered to be one of an acute gastro-intestinal allergy rather than a peritonitis for numerous reasons. The patient appeared to be in pain but he did not look toxic. The marked tache cerebrale, the past history of allergic episodes, the ingestion of a large quantity of a previously known offending food before the onset of pain, together with the history of two sisters being markedly food sensitive was presumptive evidence of an allergic reaction. This was later borne out by the finding of large numbers of eosinophiles in the mucus obtained through the proctoscope, by passive transfer of sensitivity and finally by the reproduction of identical symptoms by the specific feeding of pork. It is known that temperature reactions of varying degrees can accompany an allergic reaction (7). It is also known from leukopenic index studies that the ingestion of a food capable of producing a profound systemic shock is followed by an immediate leukopenia which in turn is frequently followed by a hyperleukocytosis which persists until food is taken again (8).

It is felt that the film of a barium enema taken during an attack of acute abdominal pain demonstrates an allergic reaction in the mucosa as well as in the muscular layers of the colon.

Phenolpthalein Administration to Nursing Women*

By

BERNARD FANTUS, M.D.

and

J. M. DYNIEWICZ

CHICAGO, ILLINOIS

THE question as to which cathartics are excreted in the milk of nursing women to a sufficient extent to affect the babe has, it seems, not been so extensively studied as the importance of the subject would justify.

Kwit and Hatcher (1) have investigated the excretion of phenolphthalein in five women who were given a single dose of from 0.03 to 0.09 Gm. of phenolphthalein and had milk drawn after intervals of six, twelve, and eighteen hours. Not one of the fifteen specimens of milk afforded a pink color after the addition of sodium hydroxide, by means of which it is possible to detect as little as 0.03 mgm.-%. They conclude that a quantity of phenolphthalein below this percentage could not exert any perceptible action on a normal infant.

AUTHORS' STUDY

In view of the practical importance of the question, it seemed desirable to repeat Kwit and Hatcher's study with certain modifications of technic in order to make the results even more conclusive, if possible. We, therefore, administered to nursing women phenolphthalein in doses ranging from 0.20 to 0.80 Gm: doses which we found these nursing women tolerated very well and in quite a proportion of cases without any resulting bowel movement.

"Yellow phenolphthalein," a product developing in the course of the manufacture of phenolphthalein and differing from the U.S.P. product in color and also with respect to certain as yet unidentified principles which it carries, has come into considerable use, as it seems to have a higher degree of cathartic action. Because of the interest which this use has created and also because even the 0.80 Gm. dose of U.S.P. phenolphthalein was not uniformly effective in securing bowel evacuation in these bed patients, we gave to another group of women this "yellow phenolphthalein" in doses of 0.30 Gm. to 0.40 Gm., which, as will be seen from the record (Table II), was quite consistent in producing bowel evacuation: the dose of 0.30 Gm. was generally sufficient.

METHOD OF STUDY

Either form of phenolphthalein was administered in form of the powder packed into capsules.

A small quantity of milk was drawn alternately from the right and the left breast of women who had been given phenolphthalein 3 or 4 hours previously. The milk was drawn in most cases both before and after nursing the babe; and, only when it became evident that there was no difference in the specimens drawn at these two times,

TABLE I

Effect of Phenolphthalein (U.S.P.) Upon Nursing Women and Their Babes

Date	Name	Dose	Effect on Mother		Effect on Baby	Free Phtn.	Conj. Phtn.

was the securing of a specimen before feeding abandoned. The study was continued for twenty-four or more hours after the giving of the dose.

The effect on the mother's and the baby's bowel movements was carefully observed and recorded.

Free phenolphthalein was searched for by the addition of N/10 sodium hydroxide V. S. to the milk. By means of this test it is possible, as stated before, to determine by the development of a distinct pink tint, the presence of as little phenolphthalein as 1 part in 3,000,000.

Conjugated phenolphthalein was searched for because it is known that a portion of the phenolphthalein that is absorbed is "conjugated," probably in the liver, by combination with certain other as yet unknown bodies. In the case of the simpler phenols, it is known that sulphate and glycuronate combinations are formed, and that such conjugation results in bodies that are largely inert biologically and that do not have the characteristic physical or chemic properties of the original substance. The determination of

12/4	L. B.	0.30	++	0	0	0	0

conjugated phenolphthalein in the milk was carried on by the following process: 5 c.c. of milk and 5 c.c. of 10% hydrochloric acid were heated on a water bath for two hours. This mixture was then transferred to a separatorly funnel and shaken out with several portions of ether. The assembled ether fractions were then shaken out with N/10 NaOH V. S.; and the amount of phenolphthalein was calculated colorimetrically.

RESULTS

It was thought best not to burden this article with a detailed report of the case studies, but merely to present in tabulated form a summary of the data secured from this investigation which included the analysis of 165 specimens of milk for free phenolphthalein and 31 tests for conjugated phenolphthalein.

Table I shows the results secured from various doses of U.S.P. phenolphthalein. Table II gives the results obtained with yellow phenolphthalein. Our results agree with those of Kwit and Hatcher in that, even with the large doses employed, *there was no free phenolphthalein in any of the milk specimens tested*, at least as far as the limits of accuracy of this test are concerned. The correctness of these results is also borne out by the fact that *none of the babies developed any diarrheal tendencies from the taking of this milk.*

We find conjugated phenolphthalein present in all the specimens secured after the administration of white phenolphthalein and 55.5 per cent of the cases of yellow phenolphthalein administration, and absent in the remainder. The obvious idea that conjugated phenolphthalein, the result of absorption, is most likely to be found the longer the phenolphthalein stays in the bowel, in other words when there is no laxative action, is not entirely borne out by our results. The quantity of conjugated phenolphthalein found in all specimens is extremely minute, ranging from 0.05 mgm.-% to 0.1 mgm.-%, with the majority at 0.05 mgm.-%. This means that there is at most 1 part in 1,000,000 and that generally it is only one-half or one-third as much. From our results we can definitely say that *conjugated phenolphthalein in these quantities is not laxative to the babe.*

CONCLUSIONS

1. No free phenolphthalein is excreted in the milk of nursing women in the course of twenty-four hours or more after the taking of large and liberal doses of phenolphthalein: of the U.S.P. as well as of the yellow variety.

2. Minute quantities of conjugated phenolphthalein are present in the large majority of all specimens of the milk of nursing women taking phenolphthalein.

3. There is no obvious effect upon the bowel movements of the babe nursed by a woman who has taken phenolphthalein.

4. Our results indicate that the yellow phenolphthalein is more active as a laxative in the bed patients studied than the U.S.P. product.*

*Our thanks are due to Dr. David S. Hills for permission to conduct this study upon his cases, and to Dr. Catherine Wyrsch, for the faithful securing of the necessary specimens and the assistance in recording of results.

SECTION VI—*Abdominal Surgery*

The Pathological Physiology of the Stomach Following Sub-Total Gastrectomy for Gastro-Duodenal Ulcer*

By

FERNANDO MILANES, M.D.†

HAVANA, CUBA

WE have recently published a paper (8), in which we reviewed the pathological physiology of ulcerous stomachs in 123 cases. Now, we present here a complementary study of 70 of those cases after sub-total gastrectomy on the same basis, in order to judge the end-results, with reference to the treatment of gastro-duodenal ulcers. The technique followed in our cases, most of them operated on by Dr. J. Lastra, was that called the "Reichel-Hoffmeister-Finsterer" method.

The purposes of this study are the following:

(a). To determine, if sub-total gastrectomy creates a gastric pathological physiology, thereby producing pathological states other than those of ulcerous stomachs, affecting the digestive and nutritional functions of the patients.

(b). To ascertain if sub-total gastrectomy diminishes or eliminates the ulcer diathesis in every case.

EXAMINATION OF OUR GASTRECTOMIZED PATIENTS

We examined every patient in two different stages:

(1). At first, we exhibited in every one, the ordinary fractional Rehfuss test extending over three hours, using E. Boas' test-breakfast.

(2). Shortly after (on a different day) we performed either: (a) the histamine and neutral red tests, in those cases indicating an "achlorhydria" at the first examination, or (b) the vagal inhibition test, in the event of having obtained at the first examination, greater or smaller quantities of "residual free hydrochloric acid." We performed the histamine (one miligram hypodermic) and neutral red (4-5 c.c. of 1% solut.) tests following the ordinary standard techniques. The vagal function test was performed, comparing the acid figures before and after the injection of one millegram of atropin sulphate. These vagal inhibition tests have been done to show the *rôle* played by the vagus in the persistence of chlorydria after sub-total gastrectomy.

RESULTS

The functional disturbances found in our 70 gastrectomized cases, examined in a period of about 3 months after operation are:

Gastric motility: Hypermotility was found in a 54% (38 cases). It was very intense in the 27% (19 cases); hypomotility was found in 29% (20 cases) of which in 6% (4 cases) it was marked; normal motility was found in 17% (12 cases).

Bile reflux: We have found bile reflux in 47% (33 cases) in the fasting stomach and in 61% (43 cases) during the digestive cycle.

Acid secretion: We found hypersecretion in 8% (5 cases), hyposecretion 21% (15 cases), and normal secretion in 71% (50 cases). We found hyperchlorydria in 17% (13 cases) in the fasting stomach and in 23% (16 cases) during the digestive phase; hypochlorydria in 9% (6 cases) in the fasting stomach and 23% (16 cases) during the digestive phase; normal acidity was noted in 6% (4 cases) in the fasting stomach and in 3% (2 cases) in the digestive phase. Finally, we found "achlorydria" in 68% (47 cases) in the fasting stomach and 47% (33 cases) during the digestive phase maintained over three hours. The average secretion (amount of juice) in the 70 cases was 21.8 c.c., and the average of acidity was: free acid 7 vols. and total acid 27 vols. We also had 4% (3 cases of variable acidity.

Histamine and Neutral Red Tests: We had 21 cases with achlorydria in which we performed these tests. We performed the histamine test in 12 cases obtaining 83% of positive histamine responses (no reappearance of acid) and 17% with histamine negative test (reappearance of acid). We performed the neutral red test in 21 cases and we detected the elimination of the colored dye in every one of the cases, but one case was considered doubtful. The average elimination time was 32 minutes and 36 seconds.

Vagal function test: Only studied in cases with persistency of hydrochloric acid. It could be performed in 22 cases. Hyper-vagotonia (marked) was found in 18% (4 cases) and slight in 55% (12 cases); total 73%. Hypo-vagotonia in 27% (6 cases), but normal

*Preliminary report. Final report to be followed in two years or so. "Cuban contribution on gastrectomies" to reach a more favorable international approach. This paper will be published in detail, including tabulations in *Archivos de Medicina Interna*, of Cuba, Vol. 2, No. 1, Jan., 1936.

†Assistant Professor of Medicine, University of Havana Medical School.

Submitted January 27, 1936.

vagus never was observed. In every case the free residual acid was modified more or less, proving evidently the main *rôle* of the vagus.

Mucous membrane condition: Alterations, including gastric cells, were present in 16% (11 cases) and without gastric cells 52% (37 cases). In 32% (22 cases), the gastric mucosa was normal. (As evidenced by microscopical sediment examinations).

All these results have been carefully noted in tabulations in our original manuscript but we are unable to include them here for lack of space. The complete records are displayed in the *Archivos de Medicina Interna.*, Vol. 2, No. 1, Jan., 1936, issued from Havana, Cuba.

COMMENT

The findings of our 70 cases of gastro-duodenal ulcer treated by sub-total gastrectomy according to the Reichel-Hoffmeister-Finsterer method, tends to show in 55% to 60% of the patients, the creation of a pathological physiology exhibiting the following principal features:

(a) Changes in motor function manifested by hypermotility and decrease of peristalis.

(b) An easily maintained bile regurgitation into the stomach.

(c) A more or less pronounced and permanent "achlorydria"; in most of the cases it does not respond to subcutanous histamine stimulation, but reacts with neutral red elimination, although the latter is somewhat delayed and of low intensity.

(d) A notable reduction of the diffuse inflammatory condition of the mucous membrane of the stomach (gastritis).

The significance of the pathological physiology of these sub-totally gastrectomized stomachs is definitely anti-ulcerous by virtue of creating a beneficial achlorydria with marked relief of the syndrome of vagal gastric irritability characterizing gastro-duodenal ulcers. The mechanism creating this curative syndrome after sub-total gastrectomy, consists in the elimination of hypervagotonia inherent to ulcers, and in the disappearance of the hormonal stimulus producing hydrochloric acid secretion, by the complete resection of the pyloric antrum. A correct technique is required and in some cases this syndrome after gastrectomy is modified by subsequent reappearance of acid secretion. In almost all these cases bearing the typical pathological physiology after sub-total gastrectomy, we have seen an absence of clinical symptomatology, particularly if additional post-operative medical treatment is followed. On the other hand, in those correctly gastrectomized cases with subsequent antiulcerous pathological physiology, a certain adaptation to the new anatomic and physiologic condition of gastric function is effected, compatible with a relatively normal digestive function. There ensues some widening of the gastric stump and in spite of the increased speed of emptying, the anastomotic loop which also widens, in its turn compensates for the relative gastric hypermotility. The alimentary contents are thus prepared properly for their satisfactory digestion. Thus it follows that there are no gross abnormalities in the stools, the indication of the deficiency of digestive function. (*Footnote*)

Footnote: This may occur more especially where Cuban patients maintain themselves on a diet which is high in carbohydrate and relatively low in animal protein and fat. Editor.

We wish to call attention to the fact that, in these correctly gastrectomized cases, the patients generally partake of a free national diet, as their social conditions will not allow them to undergo any additional dietary treatment. In the anastomized loop a true digestion, or chymification, replacing the normal one is carried out. This seems to meet the requirements of a standard digestive function. These comments refer to that 60% of cases with a normal course subtotal gastrectomy which has not met technical, operatory difficulties nor immediate or subsequent complications. We shall now discuss the cases in which the observations were otherwise.

In about one-third of the cases, the above mentioned desired end-results were not obtained. Another pathological physiology occurs closely resembling that of genuine gastro-duodenal ulcer. In these other cases, we observed a persistency of hypersecretion and hyperchlorydria accompanied by hypomotility and food retention. In other instances, there was a greater or lesser persistence of acidity varying in degree, and the clinical ulcerous sympthomatology reappeared sooner or later. In many of these cases, we proved that the operative technique had been faulty; however even after a quite correct operation, no anti-ulcerous pathological physiology was created and the condition remained like that in gastro-duodenal ulcer. These cases (25 to 33% of our series) justify the doubt of the surgeons who are opposed to sub-total gastrectomy, as to whether this procedure is capable of assuring an antiulcerous post-operative condition. The frequency of peptic ulcer formation, inflammatory constriction of the stoma, periviscerítis of the anastomotic opening, saccular dilatation, erosive residual hyperacid gastritis, etc., after gastrectomies performed by quite competent surgeons, make one doubt the advisability of considering sub-total gastrectomy a standard procedure for the treatment of gastro-duodenal ulcers. On the other hand, we are encouraged by the success obtained in most of our cases by our surgeons who have specialized in this type of sub-total gastrectomy. Referring to the truly inmediate surgical complications of gastrectomy, we must stress the point, that they ought not to be considered contra-indications as we have encountered few of these cases. The presence of paralytic ileus, hemorrhages and stump perforation in the postoperative records of our gastrectomized patients are very rare at present in our country.

In summarizing these considerations, we can affirm that because of the creation of an evidently antiulcerous pathological physiology, this type of sub-total gastrectomy appears to be the most effective operation, in view of its results, in the treatment of gastro-duodenal ulcers, when performed by specialized surgeons. Of course, it should be performed only on evidently established ulcers beyond the mucosa or accompanied by such complications as hemorrhage, perigastritis, etc. Gastrectomy should always be followed by adequate anti-ulcer medical treatment to facilitate the adaptation to the newly created anatomic physiologic conditions of the gastrectomized stomach and to avoid a deficiency of digestive and nutritional functions. Gastrectomy, performed by the average surgeon, who is not possessed of specialization in this type of operative technique, does not produce equally satisfactory results though it always proves to be superior to any

other conservative procedures in the surgical treatment of ulcers. After experience with all the conservative operations, particularly gastro-enterostomy, we found a persistency of the ulcerous pathological physiologic syndrome under the same or worse conditions.

CONCLUSIONS

1. To investigate the pathogenesis and therapy of gastro-duodenal ulcer, we studied by gastric intubation 70 cases in whom sub-total gastrectomy had been performed employing the technique of Reichel-Hoffmeister-Finsterer.

2. A complementary study of the gastrectomized patients with achlorhydria was accomplished by means of the neutral red and the histamine tests.

3. Particular attention was paid to the gastrectomized cases who exhibited persistent free hydrochloric acid in varying degrees, by means of the vagal inhibition test employing atropin.

4. We have summarized our findings and have presented as well, detailed comments on our findings according to the different functions (motility, bile reflex, secretion, chlorhydria, etc.), and have commented particularly on the data obtained through the neutral red, histamine, and vagal inhibition tests.

5. Alterations were found in 55-60% of the cases; these were characterized by hypermotility, pyloric insufficiency, changes in the gastric mucosa and achlorhydria. These achlorhydrias have, in 83% of the cases, positive histamine reactions (without appearance of free hydrochloric acid) and in 95% negative reactions to the neutral red elimination test thus proving them to be functional achlorhydria due to inhibition. This group of cases had been operated on mostly by our specialized surgeons.

6. The alterations found in 25-30% of the cases were characterized by persistency of free hydrochloric acid, and in many cases, by a marked hyperchlorhydria, hypomotility, with food retention and slight gastritis. The vagal inhibition test by the subcutaneous injection of one mgm. of atropin sulphate proved the active *rôle* of the vagus in the causative mechanism of residual chlorhydric acidity. Most of these cases had been operated on by very capable surgeons, though not specialized in gastrectomy.

7. Gastrectomy after the Reichel-Hoffmeister-Finsterer method acts as an anti-pathogenic operation for ulcer, by creating a genuine anti-ulcerous pathological physiology, particularly when performed with a correct technique and with a resultant good anastomotic opening. The resection of the pyloric antrum and vagal fibers ought to be as complete as possible in order to eliminate the hormonal and stimulating factors of the hydrochloric acid secretion.

8. A satisfactory adaptation to the newly created anatomy and physiology, with the assurance of a relatively normal digestive nutritional function is achieved.

9. It is advisable post-operatively to institute a complementary medical treatment directed against the ulcer diathesis and to facilitate the functional adaptation of the gastrectomized stomach.

10. Finally, sub-total gastrectomy appears to be the surgical intervention of choice; it is far superior to any of the various conservative procedures (gastro-enterostomy, etc.) for the surgical treatment of gastro-duodenal ulcers, though the best results are obtained when the operations are performed by surgeons who have specialized in this type of operation. The effects of sub-total gastrectomy even when performed with the best technique, are not completely adequate. There is always required a complementary medical treatment at the hands of one capable of appreciating the conditions present and capable of proper exhibition of that treatment.

SECTION VII—*Surgery of the Lower Colon and Rectum*

Anal Cryptitis

By

PAUL C. BLAISDELL, M.D.
PASADENA, CALIFORNIA

ANAL cryptitis is one of the commonest lesions causing, directly or indirectly, local anal symptoms. Directly, it is the source of prevalent subjective complaint; indirectly, because it is the essential nidus in the pathogenesis of the great majority of anal fistulas and their immediate sequelae, peri-anal abscesses. These latter conditions would, in other words, be comparatively rare but for the antecedent cryptitis. Furthermore, in contradistinction to other anal lesions, which may for the most part be recognized by palpation or inspection, the identification of crypts is not so

Submitted November 11, 1935.

simple, and requires more experienced search. If rectal carcinoma, for example, is so frequently overlooked because of failure to make even a cursory digital examination, how much more frequently must the more hidden secrets of anal pathology fail of revelation. For all of these reasons the topic would seem to justify more consideration than has in the past been accorded it.

We shall not interest ourselves at this time in the mentioned sequelae of cryptitis but only the uncomplicated lesion itself. And as further limitation I shall confine my notes largely to clinical considerations, and particularly as related to my own observations.

As an *anatomical and pathological introduction,* however, one should be familiar with the recent article of Tucker and Hellwig (3), which I particularly commend as a valuable and scholarly contribution toward a basic understanding of the condition. As an explanation of the *frequency* and *persistency* of cryptitis, these investigators have demonstrated the presence of preformed epithelial lined ducts, regarded as the remains of complex glandular organs as found in the lower orders of mammals, which open into the crypts of Morgagni and afford a ready path for infection. The infection was found to be primary in these ducts rather than in the crypts proper. The epithelial lining and poor drainage explain the failure to heal of themselves or with conservative measures, in conformity with generally recognized surgical principles. With one statement, however, I should like to take exception. Tucker and Hellwig state: "while the clinical importance of infected anal crypts is generally admitted—etc." I am constrained to say that their importance is not widely even *suspected,* that common knowledge regarding them is rather limited to those who are particularly interested in rectal work, and that patients may suffer for years because some little crypt is not found and eradicated. Anal cryptitis is the most frequently overlooked anal lesion.

The *local symptoms of anal cryptitis* vary within rather narrow limits. As is likewise the case with other anal conditions, complaint has usually extended over a long period of time when the physician is at last consulted, evidence of the universal antipathy for the hesitency of, rectal examinations. A crypt or several crypts, short or long, may be present without any symptoms whatsoever, and many such are found incidentally in the course of operations for other rectal conditions. The complaint for which relief is most often sought is what the patient relates to be "an irritation" and cannot further describe or classify; or it may be out and out pruritus. Either one or the other of these symptoms may be present exclusively, or they may merge one into the other at different times. As I write these lines, I am interrupted to see a boy of 19 years who has had almost constant itching for the past year. So aggravated has this been that whereas previously he had been a good student he did very poorly this year and quit school in disgust after extended treatment elsewhere. He has tried all the ointments suggested by numerous drug clerks and friends, in common with most patients who consult a proctologist. On examination, the only pathology found is a posterior crypt 1 cm. long which is determined to be, as later described, the source of his difficulty. Here, then, is a boy with a whole year of his life made useless, and possibly the whole trend of his existence influenced, by the failure previously to locate this crypt. The itching or irritation may be of a recurrent nature, appearing and disappearing at different intervals, which may vary from hours to days or weeks. I should like to emphasize this point and offer it as evidence in controversion of an elsewhere expressed opinion that pruritus is a neurosis which may be cured by the injection of a long lasting anesthetic, the latter supposedly curing the patient by diverting his mind for several days. That is, patients occasionally present themselves, who without any treatment at all have extended periods of relief, whose "vicious circles" are repeatedly broken by nature without cure. Likewise one should not be optimistic too early regarding any therapeutic procedure directed at pruritus, simple because a period of relief follows. The symptomatology of uncomplicated cryptitis does not extend to actual pain, that symptom indicating the presence of other pathology. I do not wish to imply that cryptitis is the sole cause of anal pruritus or irritation, but certainly it is a common cause.

I should like to say in passing that I do not see cases of pruritus, localized exclusively in the anal region, involving the general causes of pruritus reprinted every year in extended outline form. One can hardly pick up an article on pruritus ani without finding therein an elaborate classification of the causes: it is always the same, and is published and republished several times a year in the literature. General causes, remote, systemic, and reflex causes, are prominently displayed. No case reports are given, no claims for the relative frequency of such occurrences, no corroborative data whatsoever, but the list is always the same. A voice in the wilderness is that of Scarborough (1), who is so bold as to state that all cases are caused by pathological conditions in and around the anus. That is in keeping with my experience.

It is impossible to state with any degree of accuracy how frequently cryptitis is responsible for referred symptoms or for constituting a focus of infection. Wisely or unwisely, this is not so universally recognized a focus as the teeth and tonsils, etc., and so, many such cases may possibly be missed simply for lack of examination. Without rectal symptoms, these patients, would not of themselves, naturally, consult a proctologist. It would be the tendency of the internist, also, to overlook any such possible cases. (However I shall not say "these cases are probably more common than generally recognized." This so often used phrase is most superfluous. From the nature of things, and as long as the human mind is frail in comparison to its objective problems, the statement is true of any human ill. It should be deleted from medical literature). The recent case report of sciatica undoubtedly secondary to an anal focus of infection, reported by Smiley (2), is deserving of attention.

Usually offending crypts are quite easily located after one has acquired proficiency in anal examination in general and searching for crypts in particular, though sometimes they are located only by diligent and persistent search.

In the first place one is usually guided to the approximate location of the offending crypt by the location of the abnormal sensation or its most aggravated area, or, if extensive, the spot where it first appeared.

The responsible crypt is not found anteriorly when the symptom is posterior. Sometimes, on the other hand, it seems difficult or impossible for the patient to very accurately localize the symptom by spoken description, but he may be able to spot it with reference to a probe or other instrument placed successively on different parts of the circumference.

Then too, one is often guided by the presence of involved papillae adjacent to the crypt, they being noticeably swollen and reddened. Most frequently the offending crypt is found between two such pathological papillae.

One may enter, not just what just seems to be, but what actually is, a shallow and unoffensive crypt, and be content with letting the examination rest there. Further examination reveals what might be called a "secondary crypt," in communication with the first by a narrow neck. This secondary crypt may be narrow throughout its whole extent, an ordinary blind sinus, or may widen out so that the probe point can be swept back and forth under the skin margin for as much as a centimeter, the structures together resembling an hour glass in arrangement. The rounded head of the probe may slip easily into the secondary pocket, or it may go in with almost a snap, and the patient says, "Oh, that's tender there!", as the probe enters and is swept around. Sometimes the area is so sensitive that these secondary sinuses or extensions can only be fully entered after the area is anesthetized. Crypts may easily be overlooked in the folds of the mucosa and amongst the papillae, and only be found sometimes after repeated examinations on different occasions. The secondary extensions, too, are easily missed, due possibly to simply luck—or lack of it—but it is theoretically possible, and very probable, that the openings heal over, just like the external openings of fistulas, to break open at intervals, when they are more easily located. Whether these secondary sinuses or pockets are enlargements of the normally found ductal structures to which Tucker and Hellwig called attention, or whether they were originally but a part of the crypt and since separated by a partial or complete infective contraction, or whether they represent burrowing infections from the crypts or ducts one cannot say. Possibly they occur from various combinations. Practically, it makes little difference.

The *mode of examination* and the matter of instruments is important. The patient should be on his side, with the buttocks close to the edge of the examining table, the hips and knees bent at right angles, and the feet well away from the edge of the table so that the examiner seated on a stool can rest one elbow comfortably and with plenty of room on the table. The latter should be capable of being raised or lowered so that the position of the anus can be adjusted to eye level. The use of illumination permitting close, protracted, and comfortable scrutiny, is also essential; this cannot be accomplished by the light from a window nor by a large bulky head lamp, both of which devices do not permit close visualization. A reflecting head mirror is possible, but best of all is a small powerful light which projects from between the eyes. The Hirschman speculum gives a more satisfactory exposure of the wall of the canal then does the slide type of speculum, the wall being put on a slant corresponding to the bevel of the former instrument rather than parallel to the line of vision as with the slide type. It is important to have several sizes, and to use the largest tolerated, thus obliterating the folds of the wall making it as smooth and even as possible. Too often the attempt is made to do proctology with a single speculum or a single type of instrument. One finds the different types are valuable for different kinds of work, and it took me a long time to discover that a speculum could be manipulated as a retractor, allowing the examined side to be put on a stretch or released, as desired, thus adding considerably to the scope and thoroughness of examination.

One cannot examine satisfactorily for crypts with the ordinary operating room type of probe. It is necessary to have a long probe with a substantial handle, so that the instrument can be under adequate control with unobstructed vision. For examining (in contradistinction to operating) purposes, it is desirable to have the hook on the end rather short, about $\frac{3}{8}$ of an inch in length, and bent to a V shape rather than a U shape, and quite a wide V, the angle being slightly wider than that which the bevel of the speculum makes with the long axis of the speculum. Then about two inches toward the handle from the hook (about the length of the speculum) the shaft may be bent very *gently in the opposite direction*, a very slight angle, which helps to keep the handle out of the line of vision, and which is adjusted at the time of examination and may require changing from time to time even in the same case. These directions result in the ability to explore the side wall with *outward* pressure, rather than with a downward pull which is not in the direction of the long axis of the crypt and which results in hooking a small portion of the crypt—and so small a portion as to give the impression of a shallow and hence unoffending crypt—rather than demonstrating the crypt, with possibly a secondary pocket as described, in its demoniacal entirety. It is desirable to have at hand a number of probes of both fine and medium calibre with hooks of varying lengths from $\frac{1}{4}$ to $\frac{5}{8}$ of an inch long, and bent at different angles. For it is often inconvenient on spotting a suspicious area while slowly drawing the speculum out to have to stop and bend a probe several times until it fits the occasion. Having the various ones available in order obviates reintroducing the speculum over and over. Deliberation, care, and repeated examination are desirable, and often necessary.

Adequate treatment necessitates radical dissection of the crypt, preferably under local anesthesia. Linear incision by cryptotome or other instrument is useless, as recurrence will be inevitable. To perform the dissection expeditiously and with the least discomfort to the patient requires thought and practice.

Annual Abstracts of Proctologic Literature

(May, 1934-May, 1935) By CLEMENT L. MARTIN, M.D., Chicago, Illinois

The complete bibliography from which these Abstracts were made will be published in full in the Transactions of the American Proctologic Society, 1935.

CHRONIC ULCERATIVE COLITIS

A very worthy contribution to this contentious subject is contained in the *Sibrand Lups'* thesis for his doctor's degree in medicine at Gronigen. It has been translated into English by Dr. A. J. Baker and appears in the *American Journal of Digestive Diseases and Nutrition.* Since 1922 when *Bargen's* work stimulated discussion of the disease and consequently more papers on it appeared, I have seen no more thorough and constructive a report of an investigation of the subject. His findings on animal innoculations, carefully controlled, support *Bargen's* conclusions as to the cause of the disease. He thinks one reason why some investigators failed to confirm the latter's results is that the virulence of the organism may diminish quite rapidly. Rapid isolation and culture are necessary as Bargen has indicated.

Another factor may be the marked variability of virulence of the organism itself. The diplostreptococci Lups used were from a very acute case.

Mogena studied eleven cases with severe ulcerative colitis, in eight of these Bargen's diplostreptococcus was the only organism found.

Shwartzman does not believe that the cause of the disease is established yet. Whatever the cause is, the mucosa may become vulnerable to its flora especially *B. coli.* He has prepared an anti-toxic anti-*coli* horse serum of high neutralizing titre as determined by means of local skin reactivity to *B. coli.* Of 21 cases treated with the serum he reports good results in 18 of 21 cases, failure in 3.

Felsen believes the cause of the disease is still unknown and states "it appears that some cases are the end result of a bacillary dysentery."

Bastedo suggests "At this stage (of our knowledge) might we not properly reclassify our cases into: ulcerative colitis with dysentery agglutinations and ulcerative colitis without dysentery agglutinations . . . . . ."

Thaysen writes on simple hemorrhagic proctitis and proctosigmoiditis divorcing it from chronic ulcerative colitis. Admitting there are cases which are mild, do not progress and are cured, this classification appears to me a step backward.

CYSTS

Enterogenous. *McLanahan & Stone* report two cases of enterogenous cysts associated with the rectum. The case histories are given; one patient was a woman of 48 years, the other a one-month-old boy. The majority of previously reported cases were of cysts in the ileocecal region.

In their own cases the cyst lining was definitely enteric. In their discussion the work of Evans, who emphasized the great preponderance of intestinal diverticula in early life, and Lewis and Thyng, who 25 years ago demonstrated the epithelial origin of these diverticula in the pig, rabbit and human embryos, is cited. The origin of enterogenous cysts is thought to be in these small diverticula and so it becomes easy to understand that such cysts and diverticula may in reality be different phases of the same process; thus it is not difficult to explain on the above basis the location of a cyst in the intestinal wall, be it submucosal, intermuscular or subserous. In addition, the tumor may lie at any point in the gut periphery, ante-mesenteric, mesenteric, or at an intermediate site. Many lie between the folds of the mesentery.

In a case report by *Hughes-Jones* of enterogenous cyst, the etiology is discussed from the standpoint of the origin of the diverticulum and from the basis of sequestration. *Pattison* writes of 6 cases of malignant lymphoma. The localized type is of special interest to the surgeon.

Cysts, Pilonidal. Twenty-one cases of pilonidal cyst were treated by *Ferguson.* After excision he used primary suture and had but one failure.

Oldham states he has had 100% cure in 19 cases of coccygeal sinus since 1933 by primary union following excision and suture with non-absorbable sutures.

Cattell excises the sinus after marking out a triangular flap. Excision is carried out, the flap mobilized and the wound sutured, closing the flap horizontally and longitudinally. My own experience with primary suture has convinced me that it has definite limitations. When once the incision becomes infected, as it very commonly does because of its site, the suture material acts as a foreign body to retain infection. Recurrence is perhaps more probable after primary union. As in any open granulating wound, a suspicious area may be curetted or excised; recurrences have been prevented in some of my own cases by careful post-operative observation. (See Transactions, 1934, Pilonidal Cyst, Rogers).

In a preliminary report of 6 cases examined by the Philadelphia post-graduate group in which pilonidal sinus or sinuses were injected with 5% methylene blue and X-rayed after Weeder's procedure, none of them showed communication with either sacrum or coccyx.

Cysts, Hydatid. Lockhart-Mummery reports a hydatid cyst of the rectum.

X-RAY

The present study, by Kantor and Schlechter, was undertaken: (1) to determine the range of mobility of the cecocolon; (2) to establish criteria for excessive fixation and excessive mobility and to report their incidence; and (3) to determine the clinical significance, if any, of these departures from the normal. The material used was an unselected series of 383 cases (190 males, 193 females). The normal vertical range of mobility of the hepatic flexure is over 1 inch to under 3 inches. Normal variation in the range of the cecum is from over 1 inch to 2½ inches. Hypermobility of the hepatic flexure may be said to exist when the vertical range is 3 inches or more, and hyperfixation when the vertical range is 1 inch or less. Hypermobility of the cecum may be said to exist when the vertical range is 2½ inches or more, and hyperfixation when the vertical range is 1 inch or less.

Excessive mobility in general occurs in 10% of cases and is associated with the asthenic habitus and with a high cecum. Excessive fixation of the hepatic flexure occurs in 28% of cases; of the cecum in 43% of cases; and of the cecocolon in 20% of cases. In general, excessive fixation is associated with low ceca or with duodenal bands. Clinically hypermotility of the hepatic flexure alone is associated with RLQ pain and tenderness and with a tendency to colonic stasis. Hypermobility of the cecum alone is associated with increased colonic irritability. Hypermobility of the cecocolon is a prerequisite for volvulus and intussusception. Clinically, hyperfixation of the hepatic flexure alone or of the cecocolon is associated with increased colonic irritability. Hyperfixation of the cecum alone is

apparently asymptomatic. The authors submit several drawings and six tables.

Kaplan outlines the types of cancer cases according to treatment facilities required, whether ambulatory, home, or hospital.

Bowing and Fricke give statistics on 500 cases of rectal carcinoma under radiation treatment. Radiation does not replace surgery but it has a distinct place in therapy of carcinoma of the anus, rectum and recto-sigmoid. Especially should the higher grade tumors be irradiated.

Weber reviews the development of gastro-intestinal Roentgen examination and stresses the importance of contrast enemas and insufflation of air following expulsion of contrast enemas in diagnosing colon conditions. Diagnostic efficiency is dependent on the examiner's familiarity with gross pathologic features of lesions as well as methods of examination.

Berg describes a method for examining the digestive mucosa by means of a thick watery suspension of opaque substance as a coating rather than a filling material. The stomach and intestine must be carefully emptied previous to examination.

DIVERTICULITIS

Various theories continue to be considered in an effort to determine the exact mode of formation of colonic diverticula. *d'Abreu* believes spasm and hyperactivity of the circular muscle of the bowel to be factors of great importance and he suggests that excessive parasympathetic action is a cause of these particularly inasmuch as relief is obtained by belladonna and hyoscyamus.

Edwards reserves surgery in diverticulitis of the colon for severe recurrent cases in which complications appear to be imminent. A right side colostomy should precede resection and should be done between attacks.

Weible suggests allowing diverticulitis of the sigmoid to go to abscess formation, then drainage being made through the anterior rectal wall by a tube extending through the anus.

Weber stresses the importance of contrast enemas after the method of Fisher and the insufflation of air following expulsion. Diagnostic efficiency is dependant upon the examiner's familiarity with the gross pathologic features of lesions as well as methods of examination.

Stewart and Illick in an article on the roentgenographic differentiation between diverticulitis and cancer of the sigmoid bring out several points of interest in a well illustrated article. They used but a pint of barium at first, examined the rectum and sigmoid thoroughly, thus avoiding confusion by other loops. The colon is then filled, and the entire procedure repeated after the patient has partially emptied the colon and again after complete defecation, often 24 hours after passing, as diverticula may be seen at this time which were not previously visible.

Lynch records a case of diverticulitis of the colon with abscess formation caused by an enema-tip injury.

FECAL IMPACTION

Stewart and Illick cite a case of obstruction from four large fecaliths and show in their article an excellent reproduction of the roentgenogram.

FISSURE, PAPILLITIS AND PECTENOSIS

The Philadelphia post-graduate group treated 4 cases of fissure by injection of Gabriel's A.B.A. solution; it proved painful and unsatisfactory in these few cases. One c.c. quinine and urea hydrochloride injections fared little better in three other cases. Using smaller amounts others have found them quite satisfactory in subacute small fissures. "Three fissures located in the posterior site were excised, after which the technic as outlined by Buie, namely, suturing the anal margin to the external sphincter muscle with catgut, was utilized. All three cases were followed by infection, and in one the sutures sloughed off."

Morgan reports 83 cases, which he operated, whose lesions could be explained by the presence of pectenosis and a pecten band. He concludes that pectenotomy is the method of choice and advises against the practice of divulsion in dealing with this condition.

PHOTOGRAPHIC AIDS IN CONSERVING SPACE IN SCIENTIFIC PERIODICALS

IT has occurred to me many times that one solution to the difficult problem of publishing long papers would be to photograph all the tables and perhaps most of the graphs and reproduce them on one or two pages. Then the occasional investigator who wants certain details or who wants to analyze the data from a new point of view can copy out what he needs with the help of a magnifying glass. In some cases the whole paper or much of it might well be photographed in the same way and only the summary be set up and printed.

Doubtless at first there would be some complaining but writers would eventually get used to the method, and would see its advantages. The other day I was talking to a physician who had had an article published in the American Journal of Digestive Diseases and Nutrition. He was most appreciative of two things. One, that his article had been sent to the printer as soon as it was received, and the other that he hadn't received any annoying letter asking him to shorten the text and to cut down on the number of illustrations. It occurred to me that in many cases a writer would be so pleased with prompt publication of his whole paper that he wouldn't gnash his teeth because his tables were reproduced in miniature.

Unfortunately, it is a rare author who realizes that few readers ever read more than the summary at the end and that even fewer examine tables or complicated illustrations. Unfortunately, also, few authors realize how costly is the setting up of tabular material.

One great advantage of shortening articles would be the possibility of publishing more papers in each issue, which would make the JOURNAL more interesting and more valuable.

I think it probable that soon many physicians will become used to seeing technical material published in miniature. Already Science Service in Washington has arranged to supply books and copies of articles at an expense of a cent a page. Each page is photo-

graphed on motion picture film, and the microscopic text is read with the help of lenses which already are available for prices as low as $1.00. Larger and more comfortable reading devices will soon be available in all libraries.*

Once a physician becomes accustomed to reading reprints about an inch square, he will think nothing of seeing parts of the original publication put out in much of the same way. These innovations are upon us, so we might as well start getting used to them. Naturally, because of difficulties in printing and imperfections in the surface of magazine paper, the degree of reduction of the illustrations in a journal can hardly be as great as it is when film is used.

Walter C. Alvarez, Rochester, Minn.

*Note: Enlargements from films are available at five cents per page. These enlargements are approximately two-thirds of the size of commonly used manuscript paper. An author may have photographed on moving-picture films his whole manuscript and print but an abstract in a periodical. When correspondents request reprints, the author refers them to the holder of the films who then make enlargements from the films at the above mentioned nominal charge. Thus a periodical conserves space by printing only complete abstracts and authors are freed from the expense of buying reprints for gratis distribution. *Editor.*

SIGNIFICANCE OF VITAMIN A DEFICIENCY

CLINICAL and experimental observations within recent years have furnished conclusive evidence that vitamin A must be considered one of the most essential factors in nutrition. Vitamin A deficiency has been recognized in the past only when it reached an advanced stage, producing extreme malnutrition, with or without xeropthalmia. More recently interest has been aroused in the milder degrees of deficiency, the "twilight zone" of vitamin lack, with borderline states as described by Salter (1). Evidence is rapidly accumulating which suggests that permanent and irreparable damage to important organs may be produced by a prolonged or slight degree of deficiency in one or more of the important vitamins.

It has been demonstrated that the retina and cornea are especially rich in vitamin A and that their health and function are governed largely by the presence of this vitamin. Deficiency in vitamin A apparently effects the epithelial tissues in a specific manner. Eusterman and Wilbur (2) note the following in this regard: "The pathological investigations of Wolbach and Howe, subsequently confirmed by various other investigators, show that there is a substitution of stratified epithelium for normal epithelium in various parts of the respiratory, alimentary and genito-urinary tracts, in the eyes and in the para-ocular glands, or, in brief, metaplasia of the greater part of the ectodermal leaf of the body. Such changes may be followed by infection in the various organs or tissues. Thus, the maintenance of intact, healthy epithelial membranes, which constitutes the first line of defense against bacterial invasion is a prophylactic function of this vitamin of the first importance."

In view of the importance of what may be termed "chronic states of vitamin A lack," it appears essential that the early signs and symptoms characteristic of the condition should be determined, and a simple method for its detection provided. It may be added that once the diagnosis is established, the use of carotene in oil (a vitamin A concentrate) furnishes an efficient and dependable means of therapy.

A few years ago the appearance of an article by Jeans and Zentmire (3) directed my attention to the use of the visual photometer as a method for the determination of the amount of vitamin A in the human. The *rationale* of this method and its application in an extensive study of the state of vitamin A balance in over 275 individuals has been described by us in an earlier communication (4). In a more recent report (5) we presented a similar study of 300 individuals made during the past year, and correlated our observations on the vitamin A balance in various pathologic states with a review of the relavent literature.

Our experience with the visual photometer suggests that this instrument furnishes a simple but accurate method for the detection of vitamin A deficiency and an easy method whereby the clinician can check the response to treatment of the condition. The hundreds of tests made under our supervision showed decided uniformity in spite of the fact that they were made with the assistance of a number of different technicians.

In a large number of subjects who were considered deficient at the initial photometric test, increased vitamin A storage indicated later at a second test following carotene therapy was always coincident with the clinical improvement. Subjects in whom the photometer indicated no improvement also failed to show clinical benefit.

One of the most interesting results of our study was the high incidence (83%) of vitamin A deficiency indicated in a group of over a hundred supposedly normal individuals, or subjects whose only complaint was lassitude, nervousness, or a general lack of a sense of well-being.

This indicates that the diet of the average individual may not be complete and suggests the importance of the addition to the diet of a vitamin A concentrate to assure an ample supply.

It seems that a more accurate and extensive study should be made of the sources vitamin A in the commonly used foods, with especial reference to the marketing of fresh fruits and vegetables, together with a more careful checking and protection of the vitamin content of canned fruits, juices and vegetables.

Another factor which may in part account for the rather widespread deficiency in both vitamins A and D is a deficiency in fats in the average diet. These vitamins are fat-soluble and are best assimilated in the presence of fats.

The supplementary use of a concentrate is especially indicated when the diet is deliberately limited for therapeutic reasons or to cause reduction in weight. It is also indicated during the following infectious processes.

When studied with the visual photometer we found that all patients who had suffered recent attacks of pneumonia, bronchitis or other acute infections were deficient in vitamin A. The majority of these showed marked improvement with large doses of carotene in oil.* The past history of many of these patients indicated that their diets had been deficient in vitamin A.

Clinically one or more of the following symptoms

*Furnished through the courtesy of the S. M. A. Corp., Cleveland, Ohio.

was noted in individuals shown by tests with the visual photometer to be deficient in vitamin A: (1). General lack of vigor. (2). Fatigue out of proportion to the difficulty of the task or the age of the individual. (3). Lack luster of the cornea. (4). Nervous irritability and loss of sleep. (5). Dryness of the hair and roughening of the skin. (6). Ptosis of the eyelids. (7). Visual difficulties similar to those which are characteristic of night blindness.

Ira O. Park, Muskogee, Oklahoma.

ALLERGY AND THERAPEUTICS

IN the course of medical practice, clinical evidences of allergy frequently crop up. So bizarre and so unexpected may be allergic manifestations, that it behooves the physician to think of them when presented with anomalies which do not conform to accepted symptom-complexes depending on what we are pleased to call "organic" lesions.

Foods, feathers, fabrics, furs, pollens, perfumes, danders, creams, lotions, dyes, shoe polishes—the list is legion—any or all, to "susceptible" persons, may account for so wide a range of transient, or even permanent, functional, pseudo-organic or, eventually organic, upsets, that practitioners must, indeed, be possessed of super-wisdom or blessed with uncanny luck, if they escape confusing allergic states with essential disease.

It is of more than passing interest that not uncommonly by the agency of the very medicaments which physicians exhibit to treat disease, allergic states may be induced, much to the annoyance of patients and often to the puzzlement of their physicians. Cornstarch in powders, wool-fat in ointments, mint or other "flavors" in solutions or tablets, rhubarb in the old stand-by, *pulv. rhei comp.*, chocolate coating common to pills—scores of drug substances or the vehicles, coatings or fluids by which they are presented to patients in "sensitive" subjects, themselves may be responsible for a host of unique local or systemic deviations from the normal. And such departures not all are ephemeral or evanescent: serious organic damage to the liver, kidneys, lung, heart muscle or central nervous system may supervene upon massive dosage or what may be considered "safe," or even minute quantities, exhibited over prolonged periods.

Nowhere is this more strikingly shown than by the disastrous effects upon the liver following the administration of the salicylates or derivatives — notably cincophen—to susceptible individuals. Here and there one even reads reports of so widely used, and for years proved harmless, drug as the cathartic, phenolphthalein, being held responsible for allergic organ-damage to a fatal degree. True it is that, in certain instances where phenolphthalein has been set forth as being responsible for death in evidently susceptible persons, other drugs—as the salicylates—or bacteria or toxic food-derivatives may have brought about fatal issue, yet, as literature accumulates, it becomes evident that in certain infrequent individuals, phenolphthalein is capable of inducing the allergic state, quite as notably as are rhubarb, aloes and similar commonly prescribed cathartic medicines. Now that physicians' attention is directed to the matter, doubtless, as data are recorded, many usually employed medicinal agents will be found to be "toxic"—in the allergic meaning. Particularly will evidence become more extensive if individuals continue to "prescribe for themselves" and drug-shop clerks—not necessarily, pharmacists, for one observes few helpers of so high a grade, professionally or in general educational rating—continue to satisfy their demands. As conditions now exist, few, indeed, are the drugs which may not be purchased without physicians' prescriptions at average drug-shops, without or with the "sales' urge" of the person behind the counter.

Especially reprehensible is it that our central, state and local governmental incumbents find scant legal restraints, (or, if there are such, they ignore them), to the indiscriminate sale of drugs to whomever wishes them. And, in these days of economic distress, self-prescribing has become a widely spread custom: from relatives, friends, the corner druggist, periodicals, the ever blatant shrieks of the radio, nay from even *doctors, sick people learn the names of drugs or preparations* and then, wholly without knowledge as to whether such are suited to whatever ails them, buy from the nearest shop.

One cannot too strongly condemn the selling to any one with the price, of those drugs available in the form of medicated "candy" or chewing gum. Such are marketed in tempting form, the dose of drug per unit may not or may be stated in the package (if it is, the print is as "fine" as are the "trick," but all-important, paragraphs common to insurance policies); radio and newspapers proclaim unblushingly their miraculous virtues and, without let or hindrance, annually a large proportion of our population buys and consumes millions of units. Is it to be wondered that overdosing, ingestion of drugs over long periods or the taking of many and often incompatible "remedies" at times—as in the recently recorded instances of "phenolphthalein poisoning"—occasionally is followed by even fatal allergic response or in the absence of that, serious injury to esential organs? Such type of consequence to indiscriminate drug-taking, to be sure, calls for cautions in the exhibition of remedies to susceptible individuals, the recognition that certain persons *are* "sensitive" to even common drugs in therapeutic dose (rarely, however, have serious effects followed the taking of commonly accepted doses) but what is demanded is that politicians and congressional lobbies cease their pernicious activities and devote whatever brains and energy they may possess properly to safeguarding our citizens. Suitable laws which actually are enforced in an honest, scientific and non-political fashion, quickly could prevent reckless and careless dispensing. Until this much-desired, perhaps Utopian, situation is established, then drug poisoning—whether

"allergic" or from preposterous dosage—can be looked for with increasing frequency.

Of especial importance is it that physicians realize the possibilities of allergic manifestation occurring and when they do occur be prepared not only to treat the disability but to recognize that the origin of the illness may be in what previously have been considered common, harmless drugs or mixtures. They *are* such, unless they chance upon a "sensitive" subject or by constant use, they produce the "sensitive" state—a situation which rarely occurs when medicines are exhibited in accordance with physicians' orders. Meanwhile, hysteric or inexperienced writers should not fill the pages of medical journals with "clinical reports"—often questionable as to accuracy — condemning medicinal agents which years of use and after millions of doses have been shown to be harmless to the major portion of the population.

Frank Smithies.

SECTION IX—*Book Reviews*

(This section is open to contributions from any medical reader, whether or not a member of the Editorial Council).

The Patient and the Weather. By William F. Petersen, Vol. I, published, 1935, by Edwards Bros., Inc., Ann Arbor, Mich. Price $3.75.

IN his preface the author states with a good deal of justification that the young physician of today, with his training centered mainly about the infections, is not mentally equipped to evaluate, is seldom curious to study, and is rarely competent to treat properly a large group of chronic diseases. There is a great tendency to assume that all men and all guinea pigs are alike in their response to infection, and finally, too little thought is given to the fact that the environment may also influence the progress and the outcome of an infection.

This first volume is intended to serve as a rapid survey of the field of meteoric medicine. The author hopes to lead the physician back to Hippocrates and the Golden Age of Greece. As he points out in the second chapter, Hippocrates paid much attention to the state of the weather during the illness of a patient. Actually, Dr. Petersen might have added that 100 years ago William Beaumont still thought it advisable to make notes of the direction of the wind whenever he was studying the stomach of Alexis St. Martin.

The volume is largely a collection of maps of the United States showing with cross-hatchings of different densities the percentage incidence of various diseases and bodily defects in the various states and in the white and negro populations. Petersen believes that these maps show a greater incidence of most diseases along the track of the storms which, originating in the region about Japan, usually follow the coast of Asia and Alaska to enter the United States around Seattle. From thence most of them sweep through the northernmost two tiers of states, leaving through Maine and Newfoundland to go across the Atlantic and through Norway, Sweden and Finland to die out in northern Russia.

Naturally, the greatest variation in the weather in this country is to be found along this track, and as a corollary of this, here we find the greatest meteorologic demand for adjustment on the part of living beings. Dr. Petersen feels, therefore, that here one should expect to find the greatest abundance of human wreckage. He believes also that this greater stress on human protoplasm in the northernmost states accounts for the fact that there the people average high in intelligence while in the less stimulating South, the incidence of feeble mindedness is large. Similarly, in some states the people are radical while in others they lean toward fundamentalism. Petersen thinks he can explain also why Vermont produces more genius but also more insanity, also why tabes and paresis are more common in certain states, and why the Negro who lives to a ripe old age in South Carolina, in the North becomes a problem for health officers.

There is no question but that the facts charted in these maps deserve much thought and study, and a man could probably spend a lifetime searching for the causes underlying the different incidence of diseases in the several states.

Although the reviewer is filled with admiration for Doctor Petersen's tremendous industry in collecting and presenting the data, and although there is much in the theory that is attractive and plausible, he cannot yet accept as even probable many of the deductions made. Actually the book would be more satisfying if Doctor Petersen had only presented his maps with the bare suggestion that possibly the storm track has something to do with some of the peculiar heavy incidences of disease in the northernmost states. An enormous amount of careful work would have to be done before any definite conclusions could be drawn, and Doctor Petersen would doubtless make more converts to his views if he were to lead his readers more gently and more surely along the ground, facing meticulously every objection and mentioning every other possible explanation for the observations made.

In all this work Dr. Petersen should have at his elbow a number of devil's advocates: one a man highly trained in the interpretation of vital statistics, another a teacher of logic, and another a careful student of trends of population in the United States. This man would know why California is full of invalids and old people, why Florida and Texas are no longer southern states, and from whence came most of the people seeking health or recreation, or oil. Dr. Petersen should have at his elbow someone to remind him constantly of how carelessly and hurriedly the draft examinations were made, and how incomplete and valueless are most of the mortality statistics based on reports by general practitioners, especially in the more backward communities. As a pathologist, Petersen must know what a tremendous difference there commonly is between the diseases that are found at a

necropsy and those which are listed on the history sheet filled in before the death of the patient.

Looking at the maps, one finds for example, that the incidence of goiter is high along the western two-thirds of the storm belt but it is very low at the eastern end. Is it not probable then, that the incidence of goiter has little to do with the weather and much more to do with the amount of iodine in the soil. Similarly, one can blame only indirectly on the storm track the tremendous incidence of tuberculosis in California, Arizona, North Carolina and New Mexico. One would be inclined to look for some decided reason for the high incidence of multiple sclerosis in drafted men from Minnesota, Michigan, Connecticut and Delaware. But does this high incidence appear also in the United States' mortality statistics, and has it been constant for any length of time? It would not seem to be due to the storm track because other states along this track are practically free from the disease.

No statistically minded person would ever feel like accepting inferences from Dr. Petersen's maps until corrections had been made for age of population and for the tendency of invalids and aged persons to crowd into certain states like California and Florida. Great care would have to be taken also to avoid drawing inferences from such facts as a high mortality from cancer or brain tumor or several of the rare diseases in Minnesota or Maryland where the presence of a large medical center attracts thousands of people close to death. It would seem that this influx of dying people must affect the mortality and morbidity statistics of some states.

Perhaps a safer and a simpler way of getting at some of these problems of meteorologic medicine would be to compare the incidence of disease in different universities within and without the storm track, as observed by able physicians in the student health services. If the reviewer remembers correctly, such a study, made years ago of the incidence of colds at the universities of Michigan and Stanford, showed no particular difference.

With all his objections, the reviewer does not wish to be understood at decrying this type of study. To him it is fascinating and well worth the labor of a life-time. He wishes Dr. Petersen well; he fears only that the doctor's tendency to blame everything including eclampsia on the weather will antagonize the very men who would gladly go along with him. It would seem a wiser course never to mention an effect of weather until the proof of the association is convincing, and all other possible explanations have been disposed of.

Walter C. Alvarez, Rochester, Minn.

SECTION XI—*Societies, Programs and Proceedings*

Thirty-Seventh Annual Meeting American Proctologic Society

Kansas City, Monday and Tuesday, May 11 and 12, 1936

HEADQUARTERS: The Kansas Citian

ARRANGEMENTS:
Dr. Fred B. Campbell, Dr. Daniel Morton,
Dr. George H. Thiele.

THE AMERICAN PROCTOLOGIC SOCIETY, organized in 1899 for the purpose of "investigating and disseminating knowledge relating to the rectum, anus and colon," is a society with a definitely limited membership, divided into Fellows, Associates, Honorary Fellows and Honorary Associates.

Regular and orthodox practitioners, members of the American Medical Association, and not affiliated with medical groups admitting those not members of the A. M. A., are hereby cordially invited to attend the 37th Annual Meeting in Kansas City, Monday and Tuesday, May 11 and 12—the week of the A. M. A. meeting.

Physicians fulfilling the above requirements who are especially interested in Proctology are eligible to submit applications for Associate Membership after attending at least one meeting of the Society and one meeting of the American Medical Association Section.

For additional information, address the Secretary.

CURTICE ROSSER, M.D., F.A.C.S.,
710 Medical Arts Bldg., Dallas, Texas.

TENTATIVE SUMMARY OF EVENTS

SUNDAY, MAY 10

12 Noon—Registration. Kansas Citian.
2 P. M.—Ride over Kansas City and environs.

MONDAY, MAY 11

8:00 A. M.—Registration. Kansas Citian
9:00 A. M.—First Scientific Session. Kansas Citian.
12:00 Noon—Luncheon. Kansas Citian.
1:30 P. M.—Second Scientific Session. Kansas Citian.

8:00 P. M.—Executive Session. Kansas Citian. Fellows only.

TUESDAY, MAY 12

8:30 A. M.—Third Scientific Session (Symposiums). Kansas Citian.

12:30 P. M.—Luncheon. Kansas Citian.

2:00 P. M.—Operative and Dry Clinics. The Kansas City General Hospital. Dr. Campbell and Associates.

8:00 P. M.—Annual Proctologic Society Dinner. K. C. Athletic Club. (Registered guests invited).

WEDNESDAY, THURSDAY, FRIDAY

Section on Gastro-enterology and Proctology, American Medical Association.

THE SCIENTIFIC PROGRAM

Presidential Address:
Dr. Frank G. Runyeon, Reading, Pa.

Report of Committee of Arrangements:
Dr. Frederick B. Campbell, Kansas City.

Memorial to Dr. Linthicum:
Dr. A. B. Graham, Indianapolis, Ind.

Review of the Literature of 1935:
Dr. Chas. E. Pope, Evanston, Ill.

Report of Committee on Physiotherapy:
Dr. E. H. Terrell, Richmond, Va.

CASE REPORTS

(Speakers are allotted five minutes, and there is no discussion).

Fistula in Ano with extension to lower limb:
Dr. Hugh Beaton, Fort Worth, Texas.

Cases of Imperforate Anus:
Dr. W. W. Green, Toledo, Ohio.

Fistula, Pilonidal Sinus, Cowperitis in one individual:
Dr. A. G. Carmel, Cincinnati, Ohio.

Cancer in Vestigial Neurenteric Canal:
Dr. Harry C. Guess, Buffalo, N. Y.

Factitial Proctitis:
Dr. Nils O. Byland, Battle Creek, Mich.

FORMAL PAPERS (15 Minutes)

The Variety and Distribution of Gross Lesions in Lymphopathia Venerea:
Dr. Collier F. Martin, Philadelphia, Pa.

Fistula in Ano (Motion picture presentation):
Dr. Dudley A. Smith, San Francisco, Calif.

Anterior Lymphatic Abscess:
Dr. Louis A. Buie, Rochester, Minn.

Drainage in Certain Anorectal Operations:
Dr. Louis J. Hirschman, Detroit, Mich.

Pruritis Ani (Report of cases treated by injection of distilled water):
Dr. Harry E. Bacon, Philadelphia, Pa.

Injection Treatment of Prolapse of the Rectum:
Dr. F. B. Bowman, Hamilton, Ontario, Canada.

Association of the Proctologic and Urinary Tracts:
Dr. Frank H. Murray, Chester, Pa.

THE SYMPOSIUMS

The Session on Tuesday morning will be set aside for three symposiums on phases of proctology of definite current importance:

DIVERTICULOSIS AND DIVERTICULITIS

Pathological Considerations:
Dr. Emsley T. Johnson, Pathologist to St. Joseph Hospital, Kansas City. (By invitation).

Clinical and Therapeutic Status of Colonic Diverticulosis:
Dr. Henry LeRoy Bockus, Professor of Gastro-Enterology, Univ. of Penn., Graduate School of Medicine, Philadelphia. (By invitation).

Surgical Management of Colonic Diverticulitis:
Dr. Thomas E. Jones, Cleveland.

Discussion opened by:
Dr. Fred Rankin, Lexington, Ky.

CAUSES OF HIGH RECTAL AND LOW BACK PAIN

Tonic Spasm of the Levator Ani, Coccygeus and Piriformis Muscles; Relationship to Coccydynia and Sciatica:
Dr. George H. Thiele, Kansas City.

Rectal Pain Associated with Sacro Illiac Strain:
Dr. Malcolm R. Hill, Los Angeles, Calif.

Discussion opened by:
Dr. Frank Dickson, Kansas City. (By invitation).

PILO-NIDAL SINUS

Etiology, Pathology, Diagnosis:
Dr. William Strobel, Duluth, Wis.

Surgical Management:
Dr. Martin S. Kleckner, Allentown, Pa.

Discussion opened by:
Dr. Walter A. Fansler, Minneapolis.

THE AMERICAN MEDICAL ASSOCIATION

In addition to the informative papers which will be heard at the annual meeting of the Society, the tentative program of the Section covering the specialty during the A. M. A. meeting immediately following indicates that the following subjects of special interest will be presented before that body:

Multiple Polyposis (McKenney)
Disseminated Polyposis (Mayo and Wakefield)
Etiology of Pruritis Ani (Tucker and Hellwig)
Surgical Treatment of Pruritis Ani (Pruitt)
Routine Colon Examination (Hirschman)
Carcinoma of the Rectum (Brindley)
Recurring Carcinoma of the Colon (Thompson)

LADIES ENTERTAINMENT

The wives of all members and guests are assured that every effort will be made by Mrs. Campbell and her Committee to add to their pleasure during the meeting of the Society.

HEADQUARTERS

The Kansas Citian Hotel. The Registration table for both doctors and their ladies will be maintained at the Kansas Citian. The usual registration fee of $5.00 will be in effect and will be applied, as is customary, to all registrants, including members of families.

THE ANNUAL TRANSACTIONS FOR 1935

have been published in one volume, which may be procured from the Editor, Dr. Herbert I. Kallet, Macabees Bldg., Detroit, upon remittance of $5.00. This volume contains a full record of all the papers and discussion of the 1935 meeting in Atlantic City, is well illustrated and handsomely bound.

SECTION XII—"*The Clinic*"

Obstipation with Long Continued Vomiting: Effect on the Teeth*

By

J. ARNOLD BARGEN, M.D.**†

and

LOUIE T. AUSTIN, D.D.S.†

ROCHESTER, MINNESOTA

A WOMAN, aged twenty-six years, who was a school teacher and a native of Mississippi, came to this clinic on June, 22, 1935, because of life-long constipation which had been very obstinate. She never had had bowel movements without the help of cathartics or enemas. As she had become older, this condition had become worse. Twelve years ago, she had begun to vomit occasionally; this had become progressively worse so that during the last six years she had vomited after nearly every meal. The last few years, the vomiting had been somewhat projectile and had occurred almost as soon as food had reached the stomach. She had consulted many physicians, without any substantial relief. Early in 1935, the value for the serum calcium had been found to be decreased and parathyroid extract and calcium gluconate had been prescribed. About the same time, injections of surgical pituitrin had been begun; these, plus an enema, had

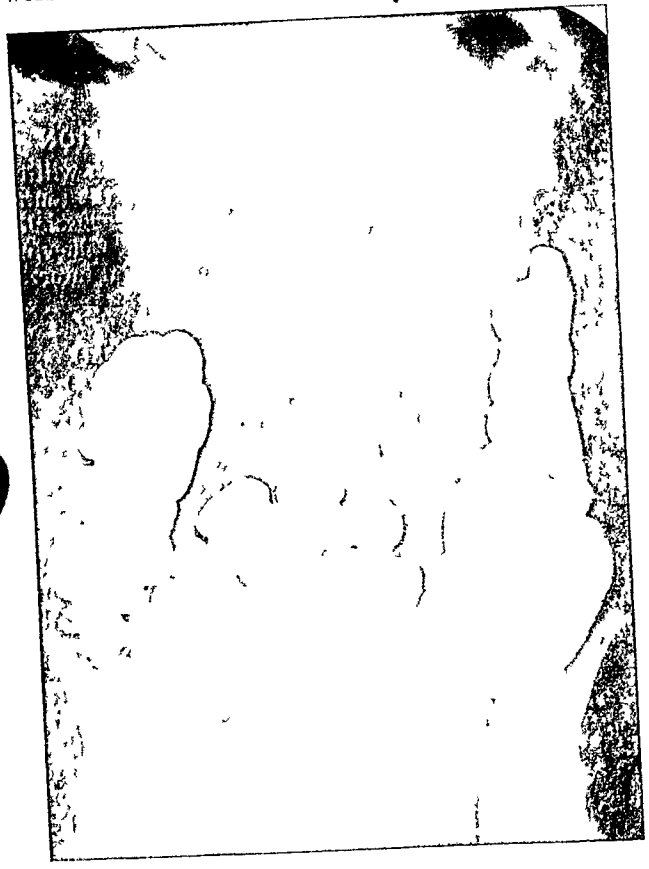

Fig 1. Elongated and dilated colon.

Fig. 2. Two views showing erosion of the anterior teeth as the result of long standing emesis.

**Division of Medicine, The Mayo Clinic
†Section on Dental Surgery, The Mayo Clinic
Submitted November 26, 1935

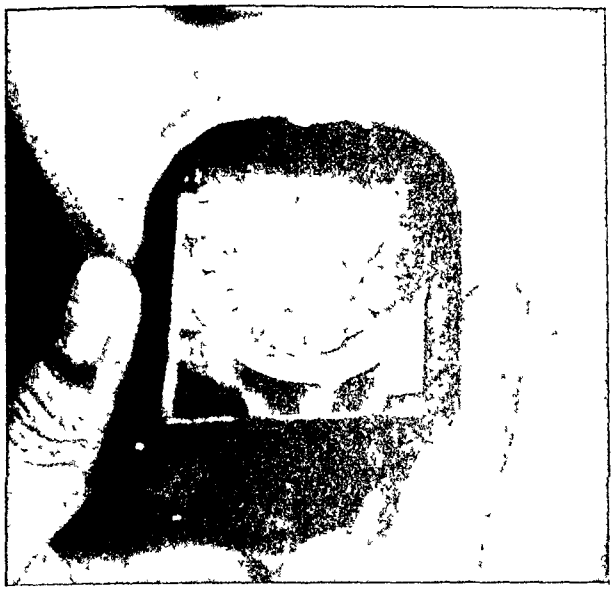

Fig. 3. Effect of long standing emesis on the teeth with fillings.

yielded bowel movements, and since the evacuations had been so much more satisfactory than they had been previously, she had continued this treatment for many months.

When she was examined at this clinic, her weight was 72 pounds (32.7 kg.) and her height was 5 feet, 4 inches (162.6 cm.). The values for the systolic and diastolic blood pressure were 92 and 58 mm. of mercury respectively. She was literally a "walking skeleton." The value for the hemoglobin was 9.7 gm. per 100 c.c. of blood. The erythrocytes numbered 3,460,000, and the leukocytes numbered 3,600 per cu. mm. of blood. A differential count of the leukocytes revealed the following values: 41.0 per cent for the lymphocytes, 4.0 per cent for the monocytes, 51.0 per cent for the polymorphonuclear neutrophils, 2.0 per cent for the eosinophils, and 1.0 per cent for the basophils. The values for the gastric acidity were 40 and 20, respectively, for the total and free hydrochloric acid with a 120 c.c. test meal, and according to the method of Topfer. Roentgenologic examination of the stomach, esophagus and duodenum did not reveal any abnormality. Roentgenologic studies of the colon showed it to be long and somewhat dilated (Fig. 1). There was no evidence of intrinsic disease. Numerous urinalyses disclosed that the urine was normal. A peculiar finding was the erosion of her anterior teeth (Fig. 2) and occlusion. One of us immediately suspected that these dental changes were the result of the continuous and repeated vomiting. It will be noted that her anterior teeth do not strike because of loss of substance, and that only her molar teeth are in occlusion. It was found that the lingual surfaces of all anterior teeth were affected, both upper and lower. The enamel had disappeared and the underlying dentine was exposed. The labial surfaces were not affected at all. The incisor teeth were shortened considerably and the incisal margins were very sharp. In the molar teeth the occlusal surfaces were chiefly involved. Fillings appeared as elevated islands of metal (Fig. 3).

The saliva had a pH of 8.0; her saliva probably had been normal at all times.

The patient became aware of the dental condition about three years ago, because of sensitivity to thermal changes and so forth, with gradual increase of discomfort. The teeth were very sensitive and protective measures were inadvisable until regurgitation was controlled. This condition is similar to erosion which results from the use of hydrochloric acid in the treatment of achlorhydria. In such cases the labial surfaces of the teeth are decalcified. It was learned that vomiting had occurred some little time after eating and that her food had been swallowed several times. Rumination is rather common among human beings, and probably not much damage is done to teeth except when it occurs at night and allows the gastric contents to remain in the mouth for a long time. The habit occasionally may be responsible for the condition spoken of as "soft teeth."

After a thorough discussion of the condition, a rigid anticonstipation diet was given. Three liters of liquid daily, and 15 drops of tincture of belladonna three times a day were given. She was also given 1/60 grain (0.0011 gm.) of physostigmine salicylate, twice a day, by mouth. The bowels began to move, the vomiting ceased, and during a period of weeks there was a gradual return of normal function. As this occurred, the administration of physostigmine salicylate was discontinued. When she was dismissed, she was advised to take a bulky type of diet and adequate amounts of liquids. During the six weeks in which this program was continued, she gained 10 pounds (4.5 kg.) and felt very well.

ABSTRACTS

CLINICAL MEDICINE

SNELL, ALBERT M.

The Effects of Chronic Disease of the Liver on the Composition and Physio-Chemical Properties of Blood; Changes in Serum Proteins; Reduction in the Oxygen Saturation of the Arterial Blood. Ann. Int. Med., IX, 690, Dec. 1935.

The author's thesis is that recognition of the unusual power of the liver to regenerate and of its very large functional capacity does not explain the freedom of symptoms in many cases in which extensive anatomical lesions exist. The studies in this paper were directed toward searching for some changes in the blood which might explain the ability of the liver to carry on when apparently showing an advanced disease in one group of cases, whereas, in another group much less anatomic changes obtain, yet all the signs and symptoms of advanced hepatic disease are found.

From these clinical observations he proceeded along two lines in search of the changes which appeared to lead to progressive disintegration of the hepatic structures, as well as, alterations in the physiological content. The studies were directed to changes in the blood in two directions, (a) the probable relation of the liver to the maintenance of serum protein; (b) the changes in the oxygen content of arterial blood, secondary to hepatic disease.

He found a fairly uniform disturbance of the normal albumin-globulin ratio, though the total proteins were not necessarily reduced; attention is invited to the rapidity with which the changes in total protein and albumin-globulin ratio occur, and he suggests that these changes possibly have some prognostic significance; that the degree of malnutrition in many cases was not conspicuous, thus making it difficult to explain the rapidity of variations on a nutritional basis; that feeding of protein had little effect on either the total serum protein or the albumin-globulin ratio. He agrees with other authors that the loss of protein through the ascitic or edema fluid does not seem to be a factor. He believes that clinical and experimental evidence seems to indicate a failure of production of protein or protein-building substances on the part of the liver with a disturbed equilibrium between the protein which is circulating and the protein which is stored. He concurs with the generally accepted belief that the reduced albumin content of blood serum of patients with hepatic disease is closely tied into the production of ascites and edema. He did not often find that the total serum proteins had been reduced to the "edema level" (4 to 5 gm. per 100 c.c.), but thinks that the disproportionate reduction in the serum albumin lowers the osmotic pressure of blood serum sufficiently to result in transudation, particularly when venous stasis occurs. He believes that such conditions as portal venous stasis and chronic peritoneal irritation play an important part in the production of ascites in hepatic disease and that the diminished serum albumin is a contributing factor only. He concludes this phase of his study with the following summary: "that one of the fairly constant effects of parenchymatous hepatic disease is reduction in the serum albumin and reversal of the albumin-globulin ratio; that these changes are most probably related to deficient production of protein by the liver, and that for this reason it may have some diagnostic and prognostic significance; and, finally, that the serum albumin is almost at or near a level which makes the production of ascites and edema relatively easy".

Turning to a discussion of the possibility of anoxemia as a factor in hepatic disease, after calling attention to the literature on the subject and describing his method and technical details, he quotes some cases upon which to predicate his theory and conclusions. The result can be no more briefly stated than to quote his own summary. "There are no constant demonstrable changes in the lung or circulation which explain the anoxemia curve in cases of advanced hepatic disease; minor degrees of edema of the alveolar walls cannot be excluded; mechanical factors such as ascites and abdominal distention are not necessary for its production; to date it has been impossible to demonstrate any variations in the physiological behaviour of hemoglobin sufficient to explain the difficulty with which the blood of these patients takes up oxygen. So far as the effects of anoxemia on the symptoms and course of the disease are concerned, it suffices to say that anoxemia, if of considerable degree and duration, can have only one effect, and that this would be an unfavorable one. It would also appear that the patient who has a chronic hepatic lesion is poorly equipped to adjust himself to even the less severe degrees of anoxemia because of the limitation in production of hemoglobin. Although the evidence is admittedly incomplete, there is much to suggest that anoxemia is at least one of the factors in which a vicious circle of progressive disintegration of the hepatic parenchyma is established."

The relation of the following problems to the anoxemia in hepatic disease is still under investigation. 1. Are there changes in the physical character of the blood which retard the rate of its oxygenation in the lung? 2. Are there hypothetical changes in the physiological behaviour of hemoglobin which can be shown only by a consideration of the time required for its complete oxygenation? 3. Is the behaviour of the pulmonary alveoli as a site for oxygenation altered in some manner, possibly by changes in the alveolar wall with resultant difficulty in diffusion of oxygen, the so-called Brauer's pneumonosis, or does the engorged or contracted liver with its mechanically altered blood flow decrease the rate of filling of the right auricle and indirectly reduce the rate of blood flow through the pulmonary capillaries, thus reducing the speed at which blood can be oxygenated?

MAYER, O. B.

Enteric Cysts. Ann. of Int. Med., Vol. IX, p. 797, Dec. 1935.

The author reports a case of an enteric cyst in a boy twelve years of age with symptoms of only a few days duration and a diagnosis made only after microscopic study. The X-ray report suggested a pancreatic tumor, possibly of a cystic nature, and the preoperative clinical diagnosis was that of a probable pancreatic cyst. This diagnosis was based on the history of an abdominal injury, the location and apparently rapid development of the tumor, the X-ray findings and a Sugar Tolerance Test.

The case is interesting because of (1) its unusual location in the transverse meso colon; (2) large size, constituting about 1/25 of the entire body weight; (3) its attachment, which permitted the removal of the cyst intact without disturbing the adjacent intestines; (4) the satisfactory postoperative convalescence.

Accompanying the report is a short reference to the nature of these cysts, the theories as to their origin and reference to some reported cases in the literature illustrating their anatomical location. These cysts are structurally similar to the intestines. They contain a mucoid substance and are lined by epithelial cells with an underlying layer of lymphoid tissue and smooth muscle.

One theory as to their origin is that they spring from a bud or pouch along the intestinal tract and another is that they are related to the more common diverticula of childhood. The majority of the cases have occurred in childhood, though some have been reported in both extremes of life. The total number reported to date is 28, the first one being reported by Franckel in 1882. The most of the cases have been found in ileocecal areas, which may be due to the fact that there is here found a remnant of the vitelline duct or yolk sac. (It is well known that when the proximal end of this pouch remains patent, the result is a typical Mechael's diverticulum.) Partly because of their rarity these cysts are seldom diagnosed except at operations.

Virgil E. Simpson, Louisville.

SIMONDS, J. P. AND JERGESON, FLOYD H. *Late Changes in the Liver Induced by Mechanical Obstruction of the Hepatic Veins. Arch. of Path., 20:4, Oct. 1935, p. 571.*

The authors have attempted to approach the subject of experimental cirrhosis of the liver from the standpoint of mechanical obstruction of the hepatic veins. They report the structural changes found in the livers of dogs as seen from the 7th to the 60th postoperative day following the mechanical obstruction of these veins for periods of from 10 to 50 minutes. They found that the dog's liver can withstand complete or almost complete stagnation of its circulation for periods of from 30 to 50 minutes with relatively slight structural changes and functional disturbance. The reason for the lack of these changes is probably the fact that the liver normally uses relatively little oxygen as compared, for instance, with that of the kidney and the brain. The amount of oxygen used by the liver of the cat, as reported by Winterstein, is about 1.1 cc. of oxygen per 100 grams per minute; that of the kidney 2½ times and that of the brain 9 times greater. Other factors may enter into this protective mechanism. The outflow from the thoracic duct is increased 2½ times during obstruction of the hepatic veins. Certain of the normal functions of the liver, such as detoxication, deamination, formation of urea and glycogenic activity may be factors protecting the hepatic cells against the effects of anoxemia.

No structural changes comparable with a true cirrhosis were produced. Certain changes were observed, however. Swelling and granulation of hepatic cells, seen frequently in the early stages, were still present in one dog on the 52nd postoperative day. Swelling of the hepatic cells from either hydropic degeneration or intracellular edema with collapse of the sinusoids remained in the later stages. Fibrosis of the walls of the central veins was evident in the later stages also. This was the only increase in connective tissue found. None of these progressive or continued degenerative changes resembled true cirrhosis of the liver.

N. W. Jones, Portland, Oregon.

EXPERIMENTAL PHYSIOLOGY

ROUQUES, LUCIEN.

"Urticaria." (A special number entirely devoted to the question in the review, "Nutrition," Paris, Tome 5, No. 1, 1935).

Urticaria to heat or cold. Pathogenesis and treatment. In these cases we have to do with a general reactivation of the organism towards cold and heat and with the vaso-motor system, excited by the colloidoclasic crisis, accompanied by a phenomenon of shock without the intervention of an extrinsec antigen. This would be due to autoanaphylacy.

Urticaria to heat. The author doubts the existence of such an urticaria, and believes these conditions belong to digestive urticaria appearing after and due to the heat of the bed or the sun, and then produced by certain spectral rays, without shock, or *would be* due to perspiration, the eruption appearing after an abundant perspiration, whatever the cause may be. The acidity of sweat is held responsible, but the *rôle* of the heat is unquestionable. A case report is given of a patient showing spells of rash or eruptions with pruritis under the influence of three factors: physical effort, mental effort (discussion, quarrel) and heat in a certain point of the body. The spells were accompanied by itching with eruption, increase in the central temperature and blood eosinophilia at 10%; cold had no effect on this patient. This case showed a reflex action of the nervous system which caused a drop of the leucocytosis from 6000 to 3000. Hemoclasia is still to be proved in those instances and instead of a casal process, we might have to do with a co-ordinated process.

Urticaria to cold. This form is observed whether after an exposure of the subject to the cold outdoor temperature, or to a local refrigeration, after the immersion of the hands in water.

Humidity and wind would be necessary with cold to have a causal effect. Some individuals reveal urticaria following river baths, whereas surf bathings produce no effect, or, when passing from warm bath into a cold atmosphere. Urticaria is produced chiefly after a sudden cold, whatever the cause may be: air, water, ice, ethyl chlorhyde, carbonic snow or ether evaporation. In all these cases cold plays a primary rôle and pathogenesis remains the same. The eruption has been noticed as superimposed on the refrigerated zone without going beyond it. No generalized eruption is noticed.

Interpretation. This condition can be considered as a local vaso-motor reaction or as phenomenon of shock.

Local reaction. Its rôle would be, in these cases, unquestionable. Eruption starts in the refrigerated zone even in a generalized rash. The origin is sympathetic. Some authors adopt a mixed theory: humoral, nervous, or perhaps cellular. One must admit with Widal, Abrami and Brissaud, that autocolloidoclasia by cold is undoubtful. According to humoral reactions, these patients can be classified in three groups.

First group: no hemoclasia. In those cases the humoral reaction is absent or not registered.

Second group: atypical reaction. The immersion of a hand or forearm in ice water is accompanied in certain patients with leucopenia, inversion of the white cell formula and hypertension. In others, hypertension is replaced by hypotension with leucopenia, without inversion, etc. An alternation between vaso-dilation and vaso-constriction is noticed. A series of observations is quoted by the author showing leucopenia on the cold side and increased leucocytes in the other members, the leucopenia passing from 12,000 to 15,800 in the left arm, after taking the right arm out of the ice, the formula coming back to normal after 12 minutes. These white cells variations are observed also in healthy individuals. Consequently, leucopenia has no signification to show evidence of a "shock" process incited by the digestive absorption of an antigen, not more than urticaria to cold incited by cold. This leucopenia by cold is merely *mechanical* and, as the author says, "the anaphylactic shock is essentially indicated by violent reactions of splanchnic origin proving a deep perturbation of the entire organo-vegetative system."

The opposition between the blood formula of the periphareal veins (leucopenia) and the central ones (absence of leucopenia) during the hemoclastic shock by cold on one hand, and hyperleucocytosis and transsitory leucocytosis on the other hand in the heart and blood vessels, is too complex a phenomenon to be explained by a simple peripheric vaso-constriction.

Third group: hemoclastic "crisis." It is revealed by leucopenia, hypotension and appearing in individuals presenting urticaria *"a frigore"* and the relations between shock and eruption are questioned by the author. In some individuals, the eruption precedes; in others, follows, crisis. From a biological standpoint, it is affirmed by the authors that the hemoclastic "crisis" must precede the clinical accidents, although cases have been observed where local urticaria appeared immediately after immersion of the member into ice, whereas, in others, it is more tardive before generalizing. In the former, it is a merely local vaso-motor reaction

caused by cold, and in the latter instance, it is the consequence of a general shock. This phenomenon is chiefly observed in patients with hemoglobinuria. A case is quoted of a man who, ducked in a cold bath, suddenly showed various troubles with collapsus and repeated lypothemias, followed by an eruption 15 minutes after the bath. Obviously, this case of tardive urticaria is due to collapsus. Frequently also, hemoglobinuria (paroxystic) with hemolysis is observed.

Urticaria to cold. Whatever the pathogenesis may be, shock to cold exists. According to certain authors (Widal) "cold suddenly dissociates certain plasmatic colloids already combined, and this sudden dislocation, in disturbing the static balance of the colloids realizes a true physical heterogeneity of the constitutional albumins and proteins, which is equivalent to a sudden introduction of foreign proteins into the blood. According to others, cold effectively reduces the formation of the proteins modified by heterogeneity, the origin of which is chemical and no more physical: there exists a true urticaria to cold, of which the tests of passive transmission demonstrate the reality."

A series of experiences realized with the serum of those patients injected to healthy individuals and followed by an application of ethyl chloride on the points of injection shows that the hypersensitiveness to cold is easily transmissible. For the authors the transmissible hypersensitiveness to cold is not of urticarian origin and they conclude: "that hypersensitiveness can be compared with the hemoclastic crisis where cold, in certain conditions of terrain, produces a local vasomotor reaction and, on the other hand, a phenomenon of "shock" resulting from the hypersensitiveness of the organism towards the proteins modified by cold; in most of the cases the local vasomotor reaction is the only intervening factor to produce the eruption and the shock had no clinical expression."

Phlogogeneous and histaminolike substances. Dermographism according to some authors is the result of a local formation of a phlogogeneous substance, as in the eruption appearing after cold, this substance coming to formation locally and playing the *rôle* of an antigen, which, combined with the "anticorps" which give birth to an eruption. Still, Vallery-Radot believes this fact is not proven, and according to him, this substance would rather be liberated by the formation of rash, which, acting as an antigen would pass into the general circulation. With Lewis, histamine already in the skin of glucose, would be liberated under the influence of multiple factors increasing the permeability of the capillaries, so that "urticaria to cold depends upon the liberation of histamin-like substances under the influence of refrigeration." Vallery-Radot refuses such a theory, and, according to him, intermediate phenomenon would exist, unknown to us, and the liberation of this histaminolike substance could be incited by the stimulation of certain splanchnic fibres. But, there again, the question is in suspense.

Treatment. The treatment, according to Rouquès, is painstaking and dubious, because there is no consistent method of success, and one must procede by successive steps. With certain individuals, atropin and policarpin are successful, whereas daily injections of adrenalin during 20 days followed by ingestion of high doses of adrenalin have stopped some urticaria to cold. Adrenalin should be administered carefully on account of general reactions. Ephedrin is comparable with adrenalin. Other substances such as jaborandi, pilocarpin atropin and belladona give inconsistent results. Some authors have suggested repeated injections of histamin, which Vallery-Radot does not believe are justified. The action of histamin is little known, and its results contradictory.

Anticlasic therapy: calcium chloride by injection, autohemotherapy and Caesium eosinate have been advised, the latter substance having a preventive action against the accidents of shock.

The *leutic treatment* has given happy results in cases of heredo-syphilis; endocrine therapy gives satisfactory results.

On the other hand, *surgery* has published interesting results where urticaria *"a frigore"* was concerned; it disappeared after the operation of a big fibroma, or after appendectomy, both causes of irritation. Favorable cases have also been reported following abundant epistaxis or repeated bleedings.

Teau LeSage, Montreal.

DEROT, MAURICE.

Urticaria Due to Effort.

The author studies respectively: 1o. The leucocytic balance; 2o. The refractometric index of the serum; 3o. The acidobasic balance and the various humoral experimental and clinical reactions already reviewed, and concludes that "after an impartial study of the various case reports on urticaria due to effort, one is easily convinced with the fact that there is no unique pathogenesis of the phenomenon. Some individuals have a colloidoclastic diathesis and will show urticaria to effort, but have or will complain of attacks of asthma, spasmodic rhinitis, even or urticaria to food. In those individuals are to be found blood reactions and hemoclastic reactions preceding the eruption; in others, probably there is urticaria of humoral origin, possibly inherent to a specific hypersensitiveness towards desintegrated proteins produced by muscular effort."

"Other cases are concerned with nervous and irritable patients showing strong vasomotor reactions. In their past, no asthma, no spasmodic rhinitis is revealed, but the physical examination will show modifications of the vago-splanchnic reactions or endocrine troubles, such as thyrotoxicosis, so that the phenomenon of humoral "shock" are concomittent with or subsequent to the eruption, but do not procede it. Such individuals show no alimentary urticaria, but are whether exclusively sensitized to efforts, or to a certain extent sensitized to other physical agents, notably heat. Urticaria of a nervous origin is held responsible in such cases, implying an hyperreactivity of the cutaneous vasomotors. Urticaria to effort seems to establish a liaison between the two large classifications of urticaria due to anaphylaxy, and urticaria due to physical agents."

Teau LeSage, Montreal.

PASTEUR, VALLERY-RADOT AND PIERRE, BLAMOUTIER.

"Treatment of the Relapsing Urticaria."

Etiologic factors are multiple: effort, cold, digestive troubles, intestinal parasites, a determined food, endocrine troubles and the vago-splanchnic imbalance. The following methods are suggested: 1o. *Autohémotherapy;* 2o *Autoserotherapy.* In the former method, 5 to 6 c.c. of blood are injected every other day, and increased gradually, but not beyond 15 c.c., that is, 8 injections altogether. In the latter case, an intraveneous puncture will give a certain amount of blood, which is left to coagulate and to transudate at the temperature of the laboratory, then the serum is aspired and injected intravenously at the dose of ½ to 2 c.c. daily or every 2nd or 3rd day, in all, 10 to 12 injections.

3o. *Peptone injections.* The Witte peptone should be used, and the injections given subcutaneously every day or every other day: 2 to 5 c.c. of 5% solution; or, every day, an intradermic injection of 1/10 to 2/10 of a c.c., from a solution at 50%, should be given, although this method is inconsistent.

4o. *Sodium hyposulphite.* May be administered *per os* or intravenously. *Per os,* 4 to 15 grams per day, in a syrup of sugar—owing to the reducting power of the latter—may have successful effects according to this formula:

Syrup of sugar	25 grams
Sodium hyposulphite	
Distilled water	aa 125 grams

A tablespoonful before each meal is given the patient during 3 or 12 consecutive days according to his tolerance, as digestive troubles may appear with

high doses: diarrhea, sulphurated belching, etc.

The intravenous method is be st;then, the solution is at 20% in distilled or sterilized water. According to Ravaut, 2 c.c. are injected the 1st time and the doses progressively increased to 30 or 40 c.c., i.e. 6 to 8 grams of the salt. In severe cases, injections may be repeated daily, three a week being sufficient, in all 10 to 12 injections.

Magnesium hyposulphite at 10%, intramuscularly, has proved very successful in resistant urticaria.

Calcium salts, such as calcium chloride at the dose of 2 to 5 grams per day are used with success in daily routine. One might use: 1o. Calcium lactate in solutions at 8%; or 2o. Calcium chloride in a 10% solution: 5 to 15 c.c. every day or every other day intravenously. Transitory uneasiness is often noticed after the latter injection: intense sensation of heat, burning sensation of the face and extremities.

Calcium gluconate is used intramuscularly or intravenously.

It is recalled by the authors that, whatever drug be used, urticaria will prove a very sensitive humoral condition. Consequently, one must be very cautions and start with small doses, administering the injection very slowly. Never should intravenous injections of peptone be given to those patients. If an acidobasic imbalance of the blood is noticed, a high dose of phosphoric acid or of sodium bicarbonate, according to the condition of alkalosis or acidosis, should logically be given.

Splenic extracts have been used with success by certain authors, then a daily injection of 2 to 4 c.c. of pork splenic extract, or of calf splenic extract, corresponding to 25 grams of fresh liver, is well indicated.

Insulin has favorable results in certain cases, although the authors report entire failure, with their personal cases. Bleeding, in relapsing cases, has given satisfactory results. Diathermy, short-wave diathermy, sulphurated oil have been tried with various results.

To combat the neuro-vegetative excitability, "*gardenal*" or *luminal* might be used: 1 centigram every second hour, or intraveneous injections or sodium bromides at 10% in cases with violent pruritis.

Local treatment consists of keeping the diseased surface sheltered from air and friction, through the medium of ointments, pastes, liniments, etc. The following formula is advised by Darier:

Gelatine	15 grams
Glycerine	25 grams
Zinc oxide	15 grams
Water Q.S. for	100 grams

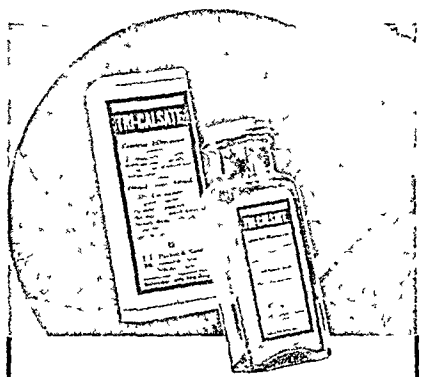
This glue is applied on the skin after liquefaction in bain-marie; then; while the substance is still sticky, the skin is covered with absorbant cotton strips, which have an adhesive action.

In conclusion: "treatment should not be carried through in a blind manner. The physician should, by a clinical study and biological examinations, strive to make out the cause of an urticaria. Only after such an investigation should the treatment be executed, and one would be especially indicated to counteract a harmful action producing the relapses of urticaria."

This monography is concluded by a study of *Urticaria and the Thermal Cure of Vichy*, by A. Mathieu de Fossey.

Teau LeSage, Montreal.

ABDOMINAL SURGERY



HINMAN, F.

A Simple Seven Suture Method of Bilateral Uretero-Intestinal Implantation. Report of 12 cases. S. G. O., Vol. 61, No. 6, pp. 802-815, Dec., 1935.

The author describes a simple seven suture method of uretero-intestinal implantation in which the probe and cautery are used. Considerable precision of execution and careful preparation of the patient are necessary.

The patient should have been on a non-residue diet for three days preceding operation. Castor oil and enemas are used to empty the intestinal tract. Through a low mid-line abdominal incision the peritoneum is incised as near the pelvic colon as possible alongside that portion into which the ureter is to be implanted. The peritoneum is now dissected away laterally elevating the ureter with it. The ureter should be carefully dissected free from that flap of peritoneum down to the juxta vesical portion which is doubly clamped, cut and ligated. The ureter on the opposite side is now prepared in the same manner and the exact sites of the implantations decided upon. The new relations must be studied carefully and a point neither too near nor too far away chosen for the point of implantation.

After the site of implantation has been decided upon it should be marked by two stay sutures. The incision in the bowel wall should be a clean cut 2.5 to 3. centimeters long between these sutures; it should extend down to but not through the submucosa and its blood vessels. The muscle and peritoneum are gently teased back and the ureter sutured to the submucosa by means of 20 day four 0 chromic catgut on a one-half circle plastic atraumatic needle. The first three sutures are placed so as to form an isosocles triangle in the submucosa. They are placed on each side of the ureter and at a point on its anterior surface; none of them are tied at this time. The ureter is incised at a point distal to the site of implantation and a probe passed into its ligated end. The three sutures are now used to elevate and hold the triangle of submucosa which is pierced with an electro cautery. The ligated

This Antacid Neutralizes HCL but does *Not* make the Stomach Contents Alkaline

TRI-CALSATE is a *buffered neutral antacid.* The buffering effect of its end salts protects against a harmful alkalosis.

NON-TOXIC and non-irritating, TRI-CALSATE may be safely prescribed even in cases which are complicated with a bowel or kidney irritation.

Extensive clinical experience proves the definite superiority of TRI-CALSATE in the treatment of hyperchlorhydria and peptic ulcer. Patients like it because it is palatable and easy to take.

Avoid the Vicious Circle

of Alkali Neutralization

Try TRI-CALSATE . . . available on prescription at your pharmacy or direct in 4 oz. and 18 oz. bottles.

ECONOMICAL

Recently the quantity in the large size bottle has been increased from 16 to 18 oz. at no increase in price, making in effect a 10% reduction in price to the patient.

TRI-CALSATE

end of the ureter is now pushed through that opening and hangs in the lumen of the bowel. The incision in the submucosa must be neither too short nor too long; it must be just the right length. Sutures No. 4 and No. 5 are used to anchor the ureter in the upper part of the muscular channel. Sutures No. 6 and No. 7 are of intestinal linen or intestinal silk. They close the lower part of the incision over the point where the ureter penetrates the submucosa. The peritoneal flap is now sutured to the bowel medial to the implantation thereby extraperitonealizing it. The opposite ureter is treated in the same manner but at a point higher or lower on the bowel. The abdomen is closed without drainage.

In the twelve cases in which the author has performed this operation *none of them developed complications* directly attributable to faulty implantation.

Twenty-eight figures accompany the article.

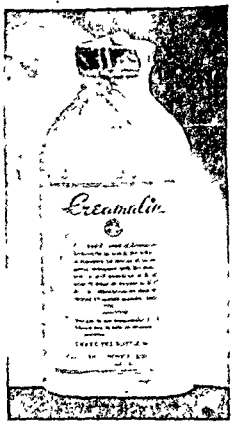
HAYMOND, H. E.

Massive Resection of the Small Intestine. S. G. O., Vol. 61, No. 5, pp. 693-705, Nov., 1935.



Resections of the small intestine have been termed "extensive" when 200 centimeters or more of its length have been excised. That constitutes about one-third of the small intestine of the average adult and is believed to be the maximum amount that can be removed with safety from a given patient.

Low Toxicity Permits EFFECTIVE Dosage

Free from Undue Influence on the Bowel

Experimental study has revealed the following index of toxicity for Decholin as compared to three commonly used bile salts: sodium taurocholate, 1:10, sodium glycocholate, 1:13; sodium cholate, 1:22. Virtual absence of toxic effect and extremely high purity permit the use of Decholin in *effective* doses, 3¾ gr. t.i.d., or q.i.d., instead of fractional grain doses of bile salts as employed in the so-termed cholagogues. The intense choleresis produced by Decholin is of proved value in chronic cholecystitis, cholangitis, hepatitis, catarrhal jaundice, and functional hepatic insufficiency and intoxication.

CLAY-ADAMS CO. WHOLESALE DISTRIBUTORS 25 EAST 26TH ST., NEW YORK

the more important conditions necessitating extensive resections were: Volvulus—76 cases; Strangulated Hernia—45 cases; Mesenteric Thrombosis—34 cases; Female pelvic disease—21 cases. Abdominal injuries and tuberculosis of the small intestine accounted for 16 cases each.

The age incidence was from 8 to 76 years. There were 156 males and 75 females. Mortality was highest in the cases in which greater lengths of intestine were resected. The operations including lateral anastomosis were the most successful.

Studies made on a number of patients who recovered showed a definite abnormal loss of nitrogen and an excess of fat in the stool. In one of the author's cases in which only 55 centimeters of small bowel remained the blood chlorides, non-protein nitrogen, carbon dioxide combining power and hydrogen ion concentration were found to be within normal limits.

Diarrhea was the most prominent and most disturbing post-operative complication in all the surviving cases. That diarrhea cannot be controlled by drugs. The patients fare best on a fat poor, protein adequate and carbohydrate rich diet.

The author reports three cases of massive resection of the small intestine. Seven tables and a very large bibliography accompany the article.

JORDAN, FERDINAND M.

"Clinical Aspects of Gastrojejunal Ulcer." Amer. Jour. of Surg., (New Series), 31:83-87, Jan., 1936.

The incidence of gastrojejunal ulcer is rather difficult to estimate, varying in different reports from 1.6 per cent to 34 per cent. Perhaps about 10 per cent would be a fairly accurate average. The appearance time of the symptoms after gastro-enterostomy is much more definite—in most cases less than a year, ranging from then until as late as nineteen years and averaging perhaps about four and a half years. It is far more likely to occur when the primary operation is performed for duodenal ulcer than when it is done for gastric ulcer. Males and nervous high-strung individuals are more commonly affected. Neglected foci of infection are definite etiological factors. High gastric acidity also contributes to the likelihood of gastrojejunal ulcer.

The symptomatology in uncomplicated cases is fairly definite. There is a recurrence of the previous symptoms with this important difference—there is usually a change in the location of the pain which in most instances is farther to the left and lower in the abdomen than previously. Vomiting frequently accompanies the pain and hemorrhage is more common. This latter symptom is especially important if the original ulcer was non-hemorrhagic. The re-

CONSTIPATION and Hepatic Insufficiency

are conditions in the correction of which a free flow of bile is essential. For nearly 25 years the medical profession has stimulated bile secretion by administering

sponse to medical ulcer management may aid in establishing the diagnosis. Roentgenologic evidence may be confusing because of the large proportion of false negative findings. Criteria relied upon are (a) the presence of a niche; (2) persistent deformity at the stoma or of the stomach or jejunum in the region of the stoma; (c) the presence of a gastrojejunocolic fistula; and (d) closure of the stoma. The condition must be differentiated from a reactivation of the original ulcer, malfunctioning gastro-enterostomy, nervous dyspepsia, and diseases of other structures. The presence of hemorrhage, perforation, or a gastro-jejuno-colic fistula adds to the difficulty of diagnosis.

Proper medical and dietary management after the first operation, and elimination of possible foci of infection may lower the incidence of this condition. The author does not favor the substitution of partial gastrectomy for gastro-enterostomy as a prophylactic measure, since that operation has a higher average mortality than the average risk of gastrojejunal ulcer after gastro-enterostomy. However, when the ulcer actually appears, partial gastrectomy is probably the operation of choice. Sometimes simple disconnection of the previous gastro-enterostomy may suffice. Medical treatment, alone, is not satisfactory.

J. Duffy Hancock, Louisville

CORFF, MEYER.

"Acute Perforated Peptic Ulcer—(A Review of Sixty-three Cases)" Amer. Jour. Surg., (New Series), 31:77-83, Jan., 1936.

In the series of cases reviewed, the author observed the characteristic sudden onset of extremely severe pain in the mid-epigastrium, accompanied by board-like rigidity of the entire abdomen. The rather pathognomonic sign of obliteration of liver dullness with elevation of the diaphragm, due to free gas in the peritoneal cavity, was not so constant as frequently reported. Eighty-five per cent of the cases gave a history of hunger pain and food relief for a year or more. The only premonitory symptom was the failure to obtain the usual food relief of the pain. The average age of the patients was thirty-seven, practically all were males, and the duodenal ulcers outnumbered the gastric five to one. The operative mortality was 25.8 per cent which is about the average.

Different types of operations were performed, several different anesthetic measures were employed, and the use of drains was varied. In this series, it appeared that the lowest mortality was obtained when simple suture of the perforation was done under spinal anesthesia and drainage instituted to the ulcer area, the pelvis, or both places. Continuous post-operative gastric drainage by the Wangensteen method was employed in all the cases. However, the greatest factor in mortality was the length of time between perforation and operation. That this is a matter of hours is clearly shown by the fact that the average time for those who lived was nine and one-half hours, for those who died thirteen and one-half hours

CANNED FOODS AND THE PUBLIC HEALTH

IV. BOTULISM

o Several of our readers have inquired as to the possibility of botulism resulting from the consumption of commercially canned foods. The canning industry is proud of the part it has played in the eradication from its products of this deadly type of food intoxication. We are glad to devote this space to a discussion of this important topic.

During recent years, the daily press periodically carries reports relating how one or more members of a family, or of a group of persons, were stricken after a meal, usually with fatal results. Sometimes these accounts describe how an "anti-toxin" was rushed to the scene—an indication that botulism was involved. These press reports often include the statement that a "canned food" was incriminated as the cause of the illness.

We wish to emphasize that as far as the records go, these outbreaks without exception are not attributed to foods commercially canned in this country. In practically every instance, it was found that the foods —usually of a non-acid or semi-acid nature —had been preserved at home by the use of inadequate heat sterilization processes (1). These press reports, by not stating correctly the type of food involved, have done much to cast unwarranted suspicion on commercially canned foods as possible causes of botulism.

Botulism, or acute toxemia due to clostridium botulinum, is by no means a new affliction. As early as 1802—ninety-five years before van Ermengem discovered the true cause of the intoxication—warnings were issued against botulism. However, not until severe outbreaks occurred in this country some fifteen years ago, was it realized that cognizance should be taken of the fact that foods canned by the methods used in those days could become contaminated with the toxin of this organism. This fact having been realized, the canning industry took immediate steps to prevent such contamination of their products.

Research was inaugurated and has been continued to which the industry has contributed not only financially, but also by the studies of scientists associated directly with the canning industry (2). The end result of these researches was the development of scientific methods of determination of heat sterilization treatments, or heat processes as they are known to the industry, which would be adequate to insure the safety of canned foods from the standpoint of botulism (3).

The effectiveness of the measures generally adopted by the canning industry of the United States is evidenced by the fact that no case of botulism attributable to an American commercially canned food has occurred during the past ten years (1a). Foods packed in commercial canneries are heat processed not only to insure protection from bacterial spoilage causing merely the loss of the food, but to render them safe from the standpoint of botulism, as well. In fact, a sterilizing process sufficient to insure the destruction of the most heat resistant strain of Cl. botulinum ever isolated is considered the minimum requirement of heat treatment of commercially canned foods. The National Canners Association has issued lists of scientifically determined processes for non-acid canned foods with which canners comply (4).

Such are the facts. The American canning industry offers its products to the consuming public for what they are: namely, wholesome and nutritious foods.

The Seal of Acceptance denotes that the statements in this advertisement are acceptable to the Committee on Foods of the American Medical Association.

be used? This is a purely surgical question.

In answer to "1": chronic ulcer belongs more to surgery than does acute ulcer, which may not recur if well treated medically. The absolute indications of surgery are: pyloric stenosis, perforation, serious hemorrhage. In these cases, surgery is imperative, the question here being one of opportuneness and of choice of method.

Relative surgical indications are painful ulcer, chronic ulcer, non-response to medical treatment and secondary anemia (hemorrhagic ulcer).

In answer to "2": What method to employ? In the non-complicated gastro-duodenal ulcer: whether to use gastro-enterostomy or extensive gastrectomy?

Gastro-enterostomy is marvellous in pre-pyloric ulcers with spasmodic stenosis and hypersecretion and in certain small ulcers of the lesser curvature. Gastroectomy is indicated in the large chronic prepyloric ulcers where malignant change is suspected; in the hard callous type of ulcer of the lesser curvature; of the old ulcer of the body of the stomach in which the base is formed by the liver or pancreas. In the ulcers placed near the cardia extensive gastrectomy is dangerous. Subtotal gastrectomy is often possible. Palliative operations are more often to be recommended such as transpyloric gastrostomy or jejunostomy.

For duodenal ulcers, experience commends simple gastro-enterostomy, if excision of the ulcer and suture of the duodenum do not seem to be of easy accomplishment.

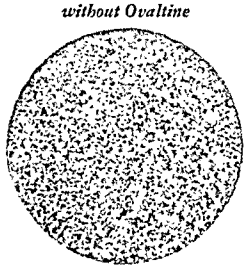
E STARR JUDD AND M. TISCHER HOFFNER, M.D.

Jejunal Ulcer. Ann. Surg., Vol. 102, No. 6, Dec., 1934.

The authors briefly review the statistics prepared by Paterson who found the incidence of jejunal ulcer to be 2.4 per cent in a series of 495 operations; and of Moynihan who reports an incidence of 1.6 per cent in a series of 613 patients who underwent gastrojejunostomy. The occurrence of the lesion varied between 1.2 and 3.2 per cent in the two series of cases published by Walton in which gastrojejunostomy was employed for duodenal ulcer. Wright reported 6 per cent while Wilkie's statistics revealed an incidence of 3.5 per cent. Heuer drawing his conclusions from his own experiences and from published reports of those of other authors says that the results of 17 authors from various countries show that recurrent or jejunal ulcer follows gastro-enterostomy in from 0.9 to 6.9 per cent of the cases, the average incidence being 3 per cent. He found that the statistics given by eight authors showed that recurrent or jejunal ulcer follows partial gastrectomy in from 0.6 to 6 per cent of cases, or an average of 1.9 per cent. This somewhat lowered incidence has been reported by many men but the authors of this paper feel that although jejunal ulcer occurs less frequently after partial gastrectomy, the operative mortality in such a procedure, when used routinely, will more than offset the increased liability to recurrent ulceration after conservative operations.

From 1906 to 1931 gastrojejunostomy has been carried out at the Mayo Clinic in 10,388 cases in the treatment of duodenal ulcer—of that number there were 251 patients who developed proven jejunal ulcer subsequent to their gastrojejunostomy which was performed at the clinic. Thus the authors report an incidence of 2.4 per cent and in the rest of their paper discuss these



FOR THE MAL-NOURISHED CHILD

MAKE "BETWEEN-MEALS MILK" MORE VALUABLE FOR HIM

MILK CURD
without Ovaltine

MILK CURD
with Ovaltine

1. INCREASE RATE OF DIGESTION
Since milk is one of those foods that is relatively slow in passing out of the stomach because of the formation of tough milk curds, why not hasten the process by producing finely comminuted curd particles? Ovaltine does this, insuring much more rapid emptying of the stomach, an earlier return of hunger, and thus a minimum of interference with the regular meal.

2. IMPROVE FOOD QUALITY
Ovaltine reinforces milk with proteins, carbohydrates and fats in easily digested form. It is also a good source of Vitamins A, B, G and D, and furnishes important minerals such as calcium, phosphorus and iron.

3. IMPROVE TASTE APPEAL
Ovaltine is delicious and makes milk more palatable and attractive to the child's taste.

cases and the problem of jejunal ulcer as to etiology, pathology, symptoms and treatment.

In classifying their cases as to age and sex, they find that the highest incidence of recurrent ulcer occurred during the third and fourth decades and that males seem to be more susceptible than females, for the proportion is at least 4 to 1 for primary ulcer, and approximately 13 to 1 for jejunal ulcer.

Jejunal ulcer may be considered, in the light of the authors findings, as a complication limited primarily to cases of duodenal ulcer in the treatment of which the jejunum has been anastamosed to the stomach, since in this series of 597 patients there were only 20 cases in which the original lesion was a gastric ulcer.

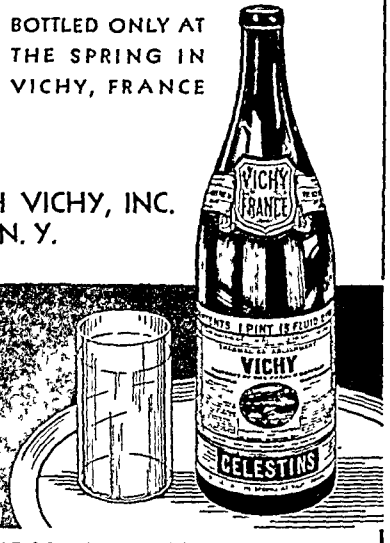
The etiology of this condition is discussed at length but the etiology remains unknown. The much discussed theories of the causation of jejunal ulcer are mentioned, among them being that of hyperchlorhydria which has perhaps the widest acceptance. The role of infection in the formation of an anastamotic ulcer is presented and the frequency with which gastritis and jejunitis is associated with these lesions is emphasized by some authors. It was formerly thought that the use of unabsorbable suture material contributed to the formation of jejunal ulcerations but this factor is ruled out by the authors who state that at the Mayo Clinic unabsorbable suture material is only very rarely used in their gastrojejunostomies.

Some of the various errors of technic which have been suggested are: (1) Too small an opening in the anastamosis; (2) Placing the stoma too high on the stomach; (3) Inclusion of inflamed gastric mucosa in the anastamosis; (4) Formation of a spur by redundant mucous membrane; (5) Invagination of the jejunum into the stomach; (6) Failure to approximate mucous membrane to mucous membrane; (7) Kinking of the distal loop; (8) Formation of a hematoma. While all of these factors must be considered and then eliminated in order to obtain satisfactory results from the operation, they do not in themselves constitute the entire answer to the problem.

The authors found that 90 per cent of the jejunal ulcers were single and that 48 per cent were situated in the line of the anastamosis. Their characteristics are similar to those ordinarily observed in peptic ulcer. If the lesion is acute the walls are soft and there is danger of perforation. However, the chronic type has thick, calloused walls and frequently has a deep crater. Owing to the proximity of the colon, it is particularly vulnerable, and if the penetrating tendency continues, a gastrojejuno colic fistula may develop as in 8.7 per cent of these cases reported.

The symptoms and signs which the authors feel are of diagnostic importance are: (1) The recurrence of pain similar though often more severe than that of the original ulcer; (2) Gastric hemorrhage, especially in the absence of bleeding before the primary operation; (3) Gross gastric retention; (4) Gastrojejunocolic fistula with its attendant symptoms, i.e. passage of watery, fatty stools, belching of gas with fecal odor, fecal vomiting, rapid loss of weight; (5) Progressive course and lack of satisfactory response to medical treatment.

In discussing the treatment of jejunal ulcer the authors first deal with the preventive treatment and state that the most effective means of preventing jejunal ulceration after the surgical treatment of peptic ulcer is to avoid gastrojejunal anastamosis in cases in



. . . of distinct service in digestive diseases

IN all forms of dyspepsia other than those arising from gastric ulcer or cancer, Vichy Celestins is of distinct service. Being easily assimilated, the water promotes gastric secretion and tends to normalize the function of the gastric glandular apparatus. In gastric neuroses and the milder forms of organic disease of the stomach, the stomach is soon physiologically improved, digestion accelerated, fermentation neutralized, and pain and nausea alleviated.

Vichy Celestins is the property of the French Republic, under whose supervision the water is bottled. The medical profession and all consumers are protected by a guarantee of the French Government as to the water's authenticity and purity.

PRINCIPAL OFFICES AND LABORATORIES, INDIANAPOLIS, INDIANA, U. S. A.

which gastric acids are high and little or no pyloric obstruction exists. "We now know that jejunal ulcer is likely to occur in individuals of this type, particularly if they are young and of a nervous high-strung temperament. Consequently, if surgical treatment of a peptic lesion becomes necessary in such cases, it is preferable to carry out some form of local operation on the duodenum and maintain normal gastrointestinal continuity whenever it can be done. For this purpose, excellent results have been obtained from excision of the lesion, together with the anterior 2/3 of the pyloric sphincter muscle, with closure as a gastro-duodenostomy. Gastrojejunostomy still constitutes an excellent form of treatment for peptic ulcer, however, for not only is the mortality low, but there is an excellent chance of cure, as 86 to 88% of the patients so treated obtain satisfactory results.

As regards the choice of operation for jejunal ulcer—the authors feel that if the primary ulcer in the stomach or duodenum has healed and the pylorus is unobstructed, the most judicious procedure may be to disconnect the gastrojejunal anastamosis and excise the jejunal ulcer. In other cases of jejunal ulcer following gastrojejunostomy, they feel that one of the following operative procedures may solve the problem: (1) Disconnection of the gastrojejunal anastomosis, resection of the jejunal ulcer, and pyloroplasty or gastro-duodenostomy; (2) Disconnection of the gastrojejunal anastomosis, excision of the jejunal ulcer and gastric resection according to the Bilroth I method; (3) Gastric resection at the level of the previous gastrojejunal anastomosis with a Polya type of reconstruction. Occasionally jejunostomy may be used to advantage either alone or in conjunction with any of the other procedures, and if patients condition is such that an extensive operation is contraindicated, simple jejunostomy may put the upper gastro-intestinal tract at complete rest until the acute phase of the disease has subsided.

Only 6 per cent of the 597 patients traced required a secondary operation for jejunal ulcer, regardless of the variations in the nature and extent of the primary surgical treatment of the jejunal lesion; however, the authors emphasize the fact that a person in whom jejunal ulcer develops very likely has a high ulcer potentiality and so should be advised to adhere to a regulated diet indefinitely and to return at intervals for a review of his condition.

MAKE CREAM OF WHEAT *an Ideal Cereal*

Cream of Wheat, prepared from the endosperm of the hard wheat berry by removal of the bran covering and the germ, ideally meets the requirements of a cereal for infants, growing children and adults. It provides an abundance of essential food elements and minerals; average analysis reveals: protein 11.8%; fat, 2.4%; carbohydrate, 72.5%; and alkaline forming ash, 0.7%. This composition, together with the 6 features enumerated below, merits preference for Cream of Wheat.

★ EASY AND RAPID DIGESTIBILITY Because of the high temperatures used in its manufacture, and since the bran covering of the wheat kernel has been removed, Cream of Wheat is quickly broken down by the amylolytic enzymes of the saliva and the pancreatic juice. Conversion to dextrose is rapid, as are subsequent absorption and utilization.

★ NUTRIENT VALUE An average serving of Cream of Wheat yields 165 calories. The addition of sugar and cream, and butter, increases the caloric value two or three-fold.

★ READILY AVAILABLE ENERGY Two hours after ingestion, 90% of the Cream of Wheat is in the small intestine undergoing conversion to dextrose. Prompt absorption rapidly replenishes the carbohydrate stores of the body.

★ PALATABILITY Its creamy consistency and appealing taste make Cream of Wheat tempting to infants, growing children, and adults alike.

★ STERILITY When prepared by cooking just prior to serving, the temperature of the boiling cereal insures complete destruction of all germ life. Thus, the effects of contamination after the package is opened, are overcome.

★ ECONOMY Cream of Wheat is an economical cereal. Its purchase price is low, and it need not be boiled for more than 15 minutes for children and adults, and 30 minutes for infants.

An interesting and informative brochure, "The Role of Carbohydrate Digestion and Metabolism in the Body Economy" will be forwarded to physicians on request Please address Cream of Wheat Corp., Minneapolis, Minnesota

Pablum is rich in minerals and vitamins. It is noteworthy that the calcium - phosphorus ratio of Pablum is 1.2:1, similar to that of average whole milk, which is considered the most favorable ratio for retention.

These figures are included to illustrate ordinary nutritional values. Calories, carbohydrates, fats, and proteins no longer constitute a serious nutritional problem.

* **The daily use of specific vehicles for vitamins C and D (e. g., orange juice for C and cod liver oil or viosterol for D) together with the use of Pablum makes it possible for the physician to supply the growing child with all of the essential vitamins in substantial quantities.

†PABLUM (Mead's Cereal, thoroughly cooked) contains nine minerals (principally calcium phosphorus, iron, and copper) and four vitamins (A, B, E, and G) in appreciable amounts—in addition to abundance of protein, fat, carbohydrate and calories. Pablum is palatable and requires no further cooking. Supplied in 1 lb. packages.

MEAD JOHNSON & CO. - - - Evansville, Indiana, U.S.A.

EXICOL

INDICATED in hepato-biliary disorders when dependable cholagogue and choleretic action is desired.

In prescribing Exicol you have the advantage of an effective therapeutic agent checked in the animal laboratory and clinically.

Exicol therapy is based on latest known and accepted physiologic principles governing the biliary apparatus.

ACTION: 1. It stimulates gall bladder evacuations (Cholagogue) and
2. Increases bile flow from the liver (Choleretic).

DOSE: 2 capsules t.i.d.a.c.

In boxes of 36 and 100.

SECTION I—*Clinical Medicine: Diseases of Digestion*

The Significance of Chronic Gastritis

By

JOSEPH W. LARIMORE, A.B., M.D.*

ST. LOUIS, MISSOURI

GASTRITIS is given a prominent place in the recent studies of the causes of several diseases, and an additional attempt at an appreciation of its actual significance seems permissible. The clinical diagnosis of chronic gastritis falls into that category of things, the affirmation of which places the burden of proof upon the skeptic. Because of repeated citation, the precursory and causal relationship of chronic gastritis to other gastric diseases is coming to be regarded as established, although the facts do not warrant such categorical conclusions. In practice, the clinical diagnosis of chronic gastritis is often inferred in the reverse direction rather than demonstrated objectively. It is insufficient to assume that, because of association, gastritis has been the cause of localized organic changes, and also, because of the suppression of secretory function, that this results from gastritis.

Any search for a common denominator is always fascinating. The discovery of a factor common to several disease entities would be a boon to preventive medicine. Hurst (1) recently said, in concluding a lecture on "Achlorhydria": "I expect that this is the last time there will be a discussion on achlorhydria, for the problem has shifted, and we must in future discuss gastritis, its causation, early diagnosis, treatment and prophylaxis, just as we discuss nephritis rather than albuminuria. It is gastritis which causes achlorhydria, and gastritis, not achlorhydria, which causes Addison's anaemia, sub-acute combined degeneration of the cord and predisposes to carcinoma of the stomach. The prophylaxis of gastritis is the prophylaxis of these diseases."

Gastritis has been demonstrated in surgical material in an almost constant association with gastric cancer and with gastric, duodenal and stomal peptic ulcers. It is also assumed and affirmed that gastritis is the underlying condition of gastric hyperacidity and of gastric anacidity. Gastric hyperacidity may have an associated erythrocythemia; achlorhydria is an almost constant accompaniment of the non-hemorrhagic anemias, and frequently it has as a sequel morning diarrhea, which may be promptly corrected by the administration of hydrochloric acid. These relationships of gastritis to other intrinsic gastric pathology, to extragastro-intestinal conditions and to systemic disease give the problem of its possible causal relationship great importance.

The generic term 'gastritis' has been loosely used and the pathological implication of the undefined term is not always clear. Its adjective qualification upon the morphologic, functional, etiologic and clinical attributes is so multiple and varied that the consequent ambiguity shows the general inadequacy of our understanding of the condition. The term is defined, however, in reference to the operative findings associated with cancer and ulcer, by description of an oedematous, reddened mucosa which microscopically has round cell infiltration involving the lymph follicles, and also an increase of the goblet cells. Submucus diapedesis of red cells and mucosal erosions may be present. Although in general discussions it is not often made clear, an atrophic type of gastritis is found in cases without cancer which clinically have shown an achlorhydria, often associated with anemia. It is not apparent that this is or is not a later stage of the follicular type of gastritis. In other discussions, the term is loosely used. It is definitely stated that gastritis denotes, not a superficial catarrhal inflammation from direct irritation, but a disease of the glandular parenchyma caused by circulating toxins. These broad pathological connotations of the term give rise to much confusion. The pathological changes and the clinical picture of disease are not static, and remote antecedents and relations are difficult to determine. The findings of gastritis, upon which the premise of an etiological relationship is based, are late pathological data and generally lack the adequate previous clinical evidence necessary to indicate the existence of the gastritis prior to the various associated diseases.

Due to these considerations, the *clinical diagnosis of gastritis* is receiving renewed and increased interest. The roentgenological study of the mucosa by its "relief" patterns, and the gastroscopic inspection of the mucosal surfaces are the chief methods of direct examination which have been recently developed. Other than these methods, the medical history, which is exceedingly ambiguous, the findings at gastric aspiration, and the thoughtful elimination of other disease form the not too-secure foundation for the clinical diagnosis of chronic gastritis. Although a deficiency of gastric juice is the most important functional finding in gastritis, it is in no sense pathognomonic. Even the diagnosis of acute gastritis depends largely upon

*Associate Professor of Clinical Medicine, Washington University Medical School.

Submitted January 17, 1936.

the positive clinical history of injurious ingestion and of the immediate revolt of the stomach. There is no clinical method of diagnosis which can, with certainty, indicate the extent, degree, or kind of mucosal inflammation by which the actual fundamental pathology may be known prior to direct study of operative or autopsy material. Eusterman (2) says, "personally, I would not like to make a diagnosis of gastritis in one of its various forms without either gastroscopic or roentgenoscopic confirmation and apparently only the hypertrophic forms of gastritis can be recognized by the latter procedure." On the other hand, others find that the clinical diagnosis is easily made by gastric lavage. It is apparent that there is no clinical method by which effectively to follow these associated "diseases" and to demonstrate with finality their pathological association or disassociation during their evolution.

Is *gastritis a causative factor* in gastric ulcer and in what manner could it be an etiological factor in duodenal ulcer? Konjetzny, Stoerk, Puhl, Bohmausson and others believe that gastritis precedes and is to be found in all cases of chronic peptic ulcer, and bring evidence to show that such lesions, existing even in the absence of ulcer-formation may give rise to symptoms typical of ulcer (3). Overgaard (4) finds that "on the basis of reports from numerous authors, it must be accepted as certain that the antrum gastritis with its accompanying acute and chronic changes forms the foundation on which typical ulcer develops." Johnston (5) finds, as previously recorded by Orator, etc., that, of surgically resected stomachs, there are approximately two-thirds exhibiting chronic follicular gastritis and one-third with simple chronic gastritis. "Follicular gastritis" (37) was recorded as associated with duodenal ulcer (18) two and one-half times as frequently as with gastric ulcer (8), not including stomal ulcers (4), and six times as frequently with gastric cancer. In four cases, no localized lesion was present. Simple chronic gastritis (18) was associated with duodenal ulcer (7) one and three-fourths times as frequently as with gastric ulcer (4), not including stomal ulcer (1) and two and one-third times as frequently with gastric cancer. In three cases, no localized lesion was found. No note is made of the pre-operative function of the stomach, that is, of gastric motility and gastric secretion. It may be suggested that impairment of motility and prolonged retention of secretions with the continuous gastric activity involved can well be, in this type of gastritis, the factor which is common to all the cases, even those in which no localized lesion was found. It is probable that the simple chronic gastritis merely is an earlier phase of a gastritis which later becomes chronic and follicular. The predominance of duodenal ulcer over gastric ulcer cannot be reconciled to the broad assertion of causal relationship when the reports consistently record gastritis with it as with gastric ulcer. If the anatomical pathology of gastritis is a causative factor in gastric ulcer, then gastric ulcer and gastritis should have a typical and inclusive association.

To further discuss this problem, a definition of peptic ulcer is necessary. The disease of peptic ulcer is fundamentally an alteration of the function of the gastro-duodenal segment into an unphysiological status which permits the development of and, by continuance, maintains the localized round ulcer lesion which is in fact only one of the abnormalities of the entire disease syndrome. The ulcer lesion is the end result of intralumenal chemical conditions produced by multiple and varied factors which allow, at the site of some injury which otherwise would heal promptly, the progressive localized destructive excavation of the wall of the stomach by necrosis and digestion. Thus is created, according to location, either duodenal ulcer or gastric ulcer. The lesion occurs and continues by reason of interference with the native healing resident in these tissues. Healing is prevented because of the prolonged digestive activity during the abnormally lengthened digestive phase which has become disproportionate to the reduced or absent quiescent phase of gastric function. Healing of the lesion is effected when the prolonged chemical processes are successfully restricted to their normal physiological period and cure of the disease is attained when the normal interdigestive phase of gastric function is restored. The fallacy of the conception that the primary agent or reason for the break in the continuity of the mucosa is also the reason for the continuance and extension of the ulcer lesion has impeded the understanding of other factors and misdirected efforts of both medical and surgical therapy.

With the premises of an acid-pepsin genesis of peptic ulcer, gastritis might be considered to operate by providing the stage-setting of gastric ulcer by reason either of hypersecretion or of the gastroparesis, which usually accompanies, and the resulting abnormal lengthening of the time-factor of active acidity. Gastritis may also be conceived to be the essential injury to the tissue which precedes the excavating processes. These possibilities presume that the gastritis is prodromal, which however, is not proved. There is often an inference that the usual hypochlorhydria of gastric ulcer is an evidence of gastritis, rather than being merely an expression of the hypotonicity of the stomach. Johnson admits the possibility that chronic follicular gastritis may exist without ulceration but is inclined to believe that it may have an etiological relation to the peptic ulcer. Arafa notes a few cases of pyloric gastritis and duodenitis which were operated upon because the symptoms were precisely similar to those of ulcer. On the other hand, Hurst (6) finds that "chronic gastritis is a comparatively common condition with a fairly definite clinical picture and a very characteristic test meal, but in my (Hurst's) experience it is rarely associated with symptoms or signs of acute or chronic gastric or duodenal ulcer."

I can find no significance in the fact that chronic follicular gastritis gives the symptoms and many of the signs of chronic ulcer, as has been emphasized by Fitzgerald (7). Except for the pain of the actual lesion or of its peritoneal extension, the symptoms and signs come from the functional impairment and derangement, and take place because it is the same organ that is impaired rather than that the diseases are necessarily etiologically related. Henning (8) has said "that so-called 'ulcer complaints' are in no way pathognomonic of ulcer." He also finds that gross bleeding occurs without ulcer as frequently as from ulcer and tumors. It has not been my experience to meet with non-ulcer gastric hemorrhage which could be explained on a gastritic basis.

If gastritis supplies the tissue injury from which excavating ulcer evolves, it is strange that duodenal ulcer exists more frequently than gastric ulcer, even

among the advanced cases of ulcer represented by the surgical material studied. That a duodenitis analogous to the gastritis is associated with duodenal ulcer, does not solve the dilemma.

It appears, if we accept the theory of the acid or peptic genesis of ulcer, that functional change extends the time of active secretion and abolishes the interdigestive rest period, which is recuperative and reparative. This is all important. Gastritis may well result from this constant presence of effective gastric juice, but the absence of gastric ulcer in so many instances of gastritis seems to point at least to the necessity of an additional accessory factor for ulcer initiation, otherwise there would be found in the material reported more gastric than duodenal ulcers.

Gastritis of various types has a frequent association with *cancer of the stomach* and that is the best support given for the hypothesis that gastritis is an essential precursor to cancer. Polland and Bloomfield (9) find that anacidity in cancer of the stomach is associated with a chronic gastritis antecedent to the growth and Bloomfield (10) states that "cancer tends to develop in stomachs already the seat of chronic gastritis with anacidity." In support of the hypothesis of an inflammatory basis for cancer, it is also asserted in analogy that chronic mastitis and glossitis precede carcinoma of the breast and tongue respectively, which statement may well be challenged. The characteristic short history of primary gastric cancer must indicate that any preceding gastritis has been asymptomatic, and it is also asserted as a fact, but without demonstrated basis, that gastritis for a long time may be asymptomatic. The reported high percentages of gastritis found with cancer can mean as yet only the coordinate association of the two diseases. Certainly, any logical deductions from established facts could indicate only that the functional disturbances of cancer are more pertinent causes for gastritis rather than is the reverse. Both the acid and anacid varieties of gastritis are prevalent disproportionately to their association with cancer in any causal relationship. Even a long clinical history of dyspepsia cannot alone support the presumption of gastritis, for generally dyspeptic symptoms arise more often from intestinal than from primary gastric conditions. Certainly, in view of the many exceptions, cancer cannot be asserted, on the basis of the rare actually observed sequence, to be a liability of gastritis of any type.

Danger arises in practice not from the certainty or likelihood of any sequence in pathology but from the very great difficulty in the clinical differentiation of the nature of prepyloric pathology as between gastritis, benign ulcer and cancer, and the frequent suggestions in prominent places of radical surgery for these cases should be correctly and frankly based upon the uncertainties of diagnosis rather than upon presumptions of any sequence in pathology. The type of gastritis associated with cancer *per se* or with the several types of cancer has no constancy. Chronic productive, interstitial gastritis with atrophy is more frequent; hypertrophic gastritis is found in some cases of adeno-carcinoma (11). It is said that gastric atrophy occurs with carcinoma of other organs through a deleterious influence on the organism as a whole. However, statistics of achlorhydria fail to show any greater increase in its incidence with age, in association with extra-gastric disease or in otherwise healthy people (12). Ewing (11) states that "the inflammatory reaction frequently meets the invasion of tumor cells. It is a highly significant feature of malignant tumor growth and must be regarded as a defensive process." This direct reaction to tumor growth must not, however, be confused with the wider mucosal inflammation which is denoted by the term 'chronic gastritis.'

In what manner may gastritis be conceived as a change precursory to malignancy of the mucosal cells? Recourse to the time-honored theory of "chronic irritation" as a cause must be used unless the direct effects of inflammation are considered a stimulus which will cause cell division to escape physiological bounds. The idea of chronic irritation may, in argument, be rationalized to indicate any form of foreign physical, chemical or bacterial action, but it has doubtless been used commonly in the sense of mechanical excitation. If the conception is, however, broadened to include any continuing stimulus to increased metabolism in the mucosal cells, it will still fail to sustain an etiological relationship which would support the precursory position of gastritis to cancer. As long as we have no recurring observations of evidence of the transition of ordinary gastritis into cancer, the significance of the gastritis as a cause of cancer is wholly unproven. The assumption that long standing achylia is an indication of gastritis helps little, for the known cases of cancer occurring after years of achylia are so rare that, considering the frequency of both diseases, their coincidence can indicate no pathological relationship.

Erskin (13) has examined the conception of irritation as the cause of cancer and cannot find support for it in known facts. He says that "if the irritation theory is to be considered tenable, the incidence of cancer should conform to three postulates: (1), Cancer should develop most frequently upon irritated areas; (2), Chronic irritation should be followed by the appearance of cancer; (3), Cancer should not appear on unirritated areas."

The assumption that tar acts merely as a chronic irritant, continued application of which causes the tissue to be the subject of malignant change, is brought into doubt by the fact that only those tars which contain carcinogenic hydrocarbons have this capacity. Further, Cook and Dodds (14) demonstrated that these hydrocarbons have also an estrogenic action. This indication that the carcinogenic effect arrives from a specific stimulus characteristic of certain molecular structures, compels the conception that for chronic irritation to be productive of cancer, it must at least develop in the tissues such a specific agent. With relation to skin cancer, Somerford (15) says "the ideal method of preventing cancer in industrial workers should be beyond the control of the workers, and among oil workers it is possible now to supply oil possessed of oil-lubricating properties without any of the carcinogenic constituents."

Macklin (16) in an excellent report of statistical analyses of clinical material gives all but conclusive support to the hereditary nature of cancer. She says: "the medical profession has laid so much stress upon chronic irritation as a factor, that it neglects the evidence of inheritance which lies before it." She, however, undoubtedly believes that an acquired disease may precipitate an hereditary one for she does not wholly dismiss the idea of chronic irritation but states further that "chronic irritation undoubtedly plays a rôle in the production of some cancers. In others it is

absent. It speeds up a reaction that is already present, to take place sooner than it would have done without the stimulus of injury." A factor of acceleration is however, not causal. On the experimental side of cancer study, Maude Slye's work is conclusive of the hereditary transmission of cancer in animals in spite of any argument whether it may be by a recessive or a dominant factor. The question of the relationship of an hereditary factor and an acquired inflammation to a precancerous condition is also present in any polyposis of the mucous membrane. It is stated by Ewing (11) that polyposis is a "feature of the late stages of catarrhal inflammation of these tissues." It is more readily conceived how a diffuse inflammation would effect an extensive diffuse polypoid hyperplasia of the affected mucosa than that it would cause a neoplasm of localized origin.

Erskin (13) voices the growing conviction when he states that "whether gastric ulcer frequently becomes cancerous is no longer in dispute, and it is now fairly well established that the incidence of gastric carcinoma is not increased among ulcer patients. It is also a fact that cancer of the duodenum is extremely rare, although duodenal ulcer is more common than gastric ulcer." The conception of the malignant degeneration of ulcer has been fostered by the idea of chronic irritation. Upon the current conceptions of the peptic genesis of ulcer there would seem to be more reason to speak of cancer-ulcer than of ulcer-cancer, since there are essentially two distinct types of gastric ulcer, the benign and the malignant ulcer; in the latter a primary cancer may provide the point of localized digestive action in an otherwise quiescent ulcer *milieu*. Their coincidence is fortuitous. It is possible, if not probable, that the abnormlly prolonged digestive action in an ulcer *milieu* could even eradicate a primary cancer and thereby effect the change of a cancer-ulcer into a benign ulcer. This is at least as probable as is Bloomfield's (10) suggestion of "two types of cancer of the stomach of fundamentally different origins" . . . . . "to be differentiated with considerable certainty by the presence or absence of acid in the gastric secretion." This conception seems to attempt to harmonize the discrepancies which arise when gastritis, in its acid and anacid types, is considered the cause of cancer.

The association of cancer and achlorhydria has long lost its diagnostic significance since the diagnosis of cancer has become more promptly and readily made and cancer is now found in an acid secreting stomach in at least one-third of the instances. Our clinical desire to observe a patient with achlorhydria for its several common associations is in reality based upon the persisting uncertainties of diagnosis rather than upon a definite likelihood of a known sequence in pathology. The development of parallel curves of incidence in the relation of cancer and achlorhydria to age is without direct significance as to their etiological relationship, and evidence, as with other diseases, only the common increase in incidence which characterizes the degenerative period of life.

The inference of gastritis from the mere findings of an achlorhydria or of an achylia is wholly untenable. It is asserted that with achylia of long duration there are always signs of gastritis, but admitting this fact, there has been no continued clinical observation of the inception and duration of either condition which would indicate the essential etiological relationship of gastritis. Bloomfield and Polland (17) find "that a lesion, which the pathologist classifies as 'gastritis' varies in extent and severity, it may be patchy or diffuse, and in any case it is not a specific lesion of anacidity, since similar changes have been found over and over again in stomachs from patients who, during life, had normal gastric secretions." Neither has the association been proven as constant. The association of chronic inflammatory changes in the stomach and of degeneration of the epithelia and glandular structure with pernicious anemia has been a persistent finding since their recognition merely as atrophy even prior to the discovery and demonstration of achlorhydria by gastric intubation. In the long period since the introduction of gastric analysis, the question of antecedence of these associated abnormalities has not been answered, and their causal or secondary relationship remains in doubt. Jones, Benedict and Hampton (18) report observations upon the gastric mucosa in pernicious anemia cases and find that, following specific therapy, evidence of atrophy and hypertrophy of the stomach, both tend to disappear. They think the correction of the atrophy results from the successful treatment of a deficiency state and the correction of the hypertrophy represents a subsidence of a chronic gastritis. This would indicate the mucosal inflammation to be secondary or at least a co-ordinate change. It is interesting to note that in ulcer cases of long duration in which gastritis may be presumed, according to surgical findings, to have co-existed, there is no development of achlorhydria. This failure is in a way unfortunate as it would provide conditions for the healing of the localized ulcer lesion and thus make the disease of peptic ulcer self-limited.

There is little opportunity in these cases of functional failure to secure histological information concurrent with the other clinical studies. Gastroscopy may be expected to help in this deficiency; however, in its practice gastroscopy will be an accessory rather than a primary or routine method of investigation. Simpson (19) says: "it is clear that the incidence of achlorhydria increases with age whether organic disease outside the stomach is present or not. In other words, there is no evidence that disease other than that of the gastric mucosa brings about achlorhydria. If evidence of organic disease is lacking, the assumption that the increasingly frequent anacidity is due to gastritis is the only logical one." To assume that secretory failure implies gastritis is to deny that secretory failure may arise from other phenomena. The question of a failure in the normal nervous and humoral stimuli has received no attention. Analogy must also imply that the functional failure of other secretory structures both internal and external must arise from inflammation. Other evidence of gastritis is usually lacking in instances of achlorhydria. That it may occur from biological protoplasmic failure is shown by the few cases in which an achlorhydria and the absence of the 'intrinsic' factor of the anti-anemia principle have been dis-associated, (20); also by the experimental findings of Babkin (21) "that in vitamin deficiency (general) there is a great impairment of the secretory response of the (dog) stomach to sham feeding, subcutaneous injection of histamine and introduction into the small intestine of food and five per cent alcohol. By the administration of yeast, normal relations were restored in a few days." This certainly demonstrates that a biological inadequacy may cause a

secretory failure. Christy (22) calls attention to the association of achlorhydria with other manifestations of nutritional deficiency and non-inflammatory primary changes in other than gastric tissues. The conception of a biological inadequacy is further supported by the occurrence of achlorhydria as a sequel to chronic debilitating diseases,—tuberculosis, malaria, colitis, dysentery, diabetes, chronic pyogenic suppurations, and is associated with asthenia, migraine, urticaria, pellagra, scorbutus and exopthalmic goitre. However, the frequent use of the term 'gastritis' to denote these changes in the parenchyma due to malnutrition, effects of pyrexia and hypothetical toxins is at best confusing.

It is impossible to believe that the demonstration of achlorhydria necessarily implies in any or all these diseases the presence of gastritis and the increased frequency of achlorhydria during the physiological stress of pregnancy suggests in that instance a systemic rather than a local cause. The same doubt may exist, of the essential occurrence of gastritis for the failure of the hemapoietic (intrinsic) factor and of the neurotropic factor, if such exists, as for the achlorhydria, in spite of the few recorded cases in which it has been demonstrated three months to twenty years prior to the diagnosis of pernicious anemia.

Macklin (16) says: "that achylia of certain types, perhaps all, is inherited, mostly in direct line of descent, passing on from parent to child," and Connor (23) having examined a large number of blood relations of pernicious anemia patients, believes that although "the results do not prove an hereditary aspect of pernicious anemia, they strongly suggest a familial tendency in the development of one of its most important features"—achlorhydria.

Faber states that chronic achylia has an exogenous cause and is produced by external factors acting on the stomach, either by direct irritation of the mucous membrane or through the blood circulation by a toxic action on the gastric parenchyma, causing not a superficial catarrhal inflammation but an effect on the glandular parenchyma. This is plainly a hypothesis and not a statement of objective fact and even as a hypothesis indicates a bio-chemical effect rather than an inflammatory reaction. A distinction must be made between a primary inflammation and a primary cell dystrophy arising either from nutritional deficiencies or from protoplasmic poisons.

Bloomfield concludes from his studies that gastritis is not a specific lesion of anacidity and, that anacidity as a precursor of or the cause of certain diseases, is possible but not finally proved by valid statistics.

That this problem of the possible sequence of gastritis to cancer, to ulcer or to the loss of mucosal secretory function is susceptible to experimental demonstration analogous to clinical occurrence, is not conceivable. It is a weakness in logic, when a condition associated with several diseases, is considered to be etiological in each connection. Causal influences and agents usually may be expected to have certain definite and predictable effects. Nothing has yet been developed in our knowledge of gastritis, to indicate any such possibility.

Howe (24) in discussing the causal fallacy, says: "there is one point, however, which every science or art must have in common with metaphysics, and that is its dependence upon some fundamental concept or elementary working hypothesis. The imposing structure of the completed edifice sometimes hides from us the fact that there must be a foundation somewhere. It is rather shaking to our scientific certainty when we realize that the nature of that foundation is nothing more secure than a hypothesis."

"The danger of a hypothesis is that it may be taken as an axiomatic statement which is therefore assumed to require no proof. There is no difficulty in checking up the error of one hypothesis by inventing others as required to fill the gaps which the original hypothesis fails to explain. This is a very general scientific tendency and accounts for the large number of hypotheses which pass as scientific facts." "A hypothesis is never at its best when used as a part of our therapeutic armamentarium but it is an essential weapon of research."

I find it impossible to harmonize the discrepancies which are found to exist when the hypothesis of gastritis as the causal precursor of peptic ulcer, cancer, achlorhydria and its association of anemia and cord degeneration, is examined. Gastritis, however, does merit in itself the revived and increased attention which is being given it.

In reviewing this hypothesis, it appears that gastritis in the sense of primary mucosal inflammation, is more likely to be in most instances a sequel or complication of peptic ulcer. In those cases in which it may have been prodromal, additional factors must be found to account for the localization of the ulcer within or without the gastritis area, factors which would, and do, operate also in the absence of gastritis. Cancer of the stomach is not in any way dependent upon or promoted by a sub-stratum of gastritis, and there has yet to be shown that there may arise from gastritis any carcinogenic factor by which an acquired disease could promote an hereditary disease. Achlorhydria and its associated secretory failures with their remote influences are more likely to arise from primary biological failure of the gland cells than to be essentially secondary to primary mucosal inflammation.

SECTION II—*Experimental Physiology*

Pancreatic Enzymes and Tissue Metabolism*†

By

H. C. BRADLEY, Ph.D.

and

SAMUEL BELFER

MADISON, WISCONSIN

RECENT articles in this Journal have ascribed to the pancreas an extraordinarily important role in metabolism. W. Boldyreff (1) states that the non-secreting tissues of the body, such as muscle, liver, spleen, etc., are unable to produce enzymes of their own and must therefore depend upon the secretions of the pancreas and intestinal glands for their supply of lipase, amylase, protease and glycolytic enzymes. The external secretion of the pancreas, according to this author, is absorbed completely from the intestine into the blood, and thus becomes in reality its internal secretion. The enzymes are then fixed by the tissue cells throughout the body. Oelgoetz, Oelgoetz, and Wittekind (2) carry the hypothesis a long step farther and state that the blood vessels constitute the main digestive organ of the body. Food and enzymes are mixed in the intestine, and together absorbed by the blood where the major steps of digestion occur. In the case of proteins, gastric and intestinal digestion may carry them through the preliminary change to acid and alkali metaproteins, but these, along with the proteolytic enzymes are absorbed as such and are finally digested in the blood. "The blood therefore may be regarded as a more important final digestive organ than is the gastro-intestinal tract." The tissues are said to contain these same enzymes, derived from the intestinal tract, and at a concentration one hundred times that found in the blood.

The three papers cited above contain little data in substantiation of the assumptions made. Boldyreff offers no data, but cites his earlier work in proving rhythmic activity along the intestinal tract as evidence in favor of the hypothesis (3). The papers by Oelgoetz, Oelgoetz, and Wittekind describe a rough method for determining the iodine absorbing power of serum, and state that this is a test for amylase. They also state without evidence that the pancreatic enzymes are always present in the blood, and in fixed proportions, so that the determination of one of them is sufficient to determine the concentration of them all.

It is not our intention to attempt a critical analysis of the details of these papers, many of which are quite counter to data in the literature. In the following paragraphs, however, we will submit concrete evidence which bears directly upon the major premise of these papers—namely, that pancreatic enzymes are present in the tissues; that tissue cells are unable to produce their own enzymes, and must depend upon the pancreas for a continually renewed supply in order to carry on the syntheses and hydrolyses incident to metabolism. If trypsin can be found in significant amount in tissues other than the pancreas, it would appear to give strong support to the hypothesis of Boldyreff. If trypsin cannot be demonstrated, it would appear to leave the hypothesis without factual justification.

We have chosen trypsin because its properties are so unique and so well characterized that there is no danger of mistaking some other proteolytic enzyme for it if the experiments are adequately controlled. The same cannot be said perhaps for lipase and amylase of the pancreas. Similar enzymes are widely distributed, and while we believe there are differences between the lipase of the pancreas and that of the liver or kidney, they are not so convincing as the differences between trypsin and other proteases.

In an earlier publication we presented some data which at the time we felt was fairly good evidence that trypsin is not one of the proteases of liver or kidney (4). In the following experiments we have again sought this enzyme under even more carefully controlled conditions. The data appears to be unequivocal and so far as it goes should definitely set at rest the question of whether pancreatic enzymes are present normally in tissues other than the pancreas.

EXPERIMENTAL PART

Hog pancreas, spleen and liver were obtained within a few minutes of the death of the animal. They were re-

*From the Laboratory of Physiological Chemistry, University of Wisconsin, Madison, Wisconsin.

Submitted January 15, 1936.

frigerated at once, ground to a smooth brei, weighed out in 50 gm. portions, and made up to a final volume of 250 c.c. in each case. Toluol was added as a preservative, care being taken to keep the digests saturated with it by frequent shaking during the first twenty-four hours. Experience has shown that under these conditions no bacterial growth occurs, and the digests remain sterile indefinitely. The digests were maintained at 37° throughout the period of study. Acid and alkali were added as indicated in the tables, and the pH levels determined potentiometrically. As has been shown previously (5), the pH values of such digests change during the period of digestion, the shift being in the direction of neutrality. The value of the pH control therefore is chiefly to determine whether the environment is satisfactory for the activity of a given enzyme or not. Trypsin is most active at about pH 8, but is still quite active at 6. On the other hand, we have previously shown (4) that typical autolytic proteases are most active in the neighborhood of 4.

Evidence of digestion was obtained as follows: twenty-five c.c. samples of the digests were removed at the start, and from time to time thereafter, as shown in the tables, run into 50 c.c. 10 per cent trichloracetic acid and made up to 100 c.c. After some hours the precipitated proteins were filtered off and the filtrate assayed for soluble N by Kjeldahl, for amino acidity by Sörensen titration, for reactive tyrosine by a modification of the Folin colorimetric method (6). Soluble N is perhaps the best method we have for measuring the rate and extent of primary cleavage of the tissue proteins. The tyrosine reaction gives essentially the same picture, because the initial breaks in the protein molecule serve to unmask most of the tyrosine (5). The Sörensen titration gives the same information, and in addition gives evidence for the further cleavage of non-precipitable protein fragments after the initial solubilizing cleavages have been completed.

RESULTS

In the data collected below we are presenting, for the sake of brevity, only the figures obtained by Sörensen titration. The other data, however, is in complete harmony with it. The experiments recorded here have been repeated many times, and are typical.

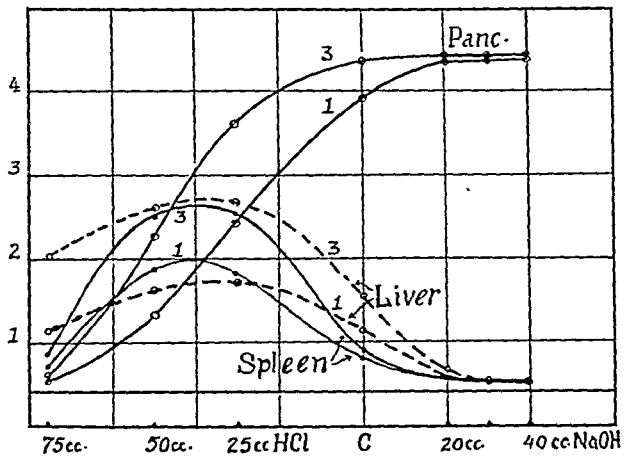
From the data above we draw the following conclusions:

TABLE I

Self-Digestion of Hog Pancreas

No.	Digests	pH Initial	c.c. N/5 amino acid in 25 c.c. trichlor. filtrate			
			Days			
			0	1st	3rd	10th
1	Control	6.16	0.40	3.90	4.45	4.50
2	Control + 25 c.c. N/5 HCl	4.48	0.40	2.80	3.90	4.10
3	Control + 50 c.c. N/5 HCl	3.35	0.40	1.30	2.25	2.90
4	Control + 75 c.c. N/5 HCl	2.57	0.40	0.60	0.65	0.70
5	Control + 20 c.c. N/5 NaOH	7.14	0.40	4.35	4.30	4.35
6	Control + 30 c.c. N/5 NaOH	7.37	0.40	4.35	4.35	4.35
7	Control + 40 c.c. N/5 NaOH	7.62	0.40	4.35	4.35	4.40

TABLE II



Hog Spleen

No.	Digests	pH Initial	c.c. N/5 amino acid in 25 c.c. trichlor. filtrate				
			Days				
			0	1st	3rd	5th	10th
1	Control	6.45	0.40	0.75	0.85	1.00	1.20
2	Control + 25 c.c. N/5 HCl	4.56	0.40	1.65	2.35	3.00	3.00

Curve 1. Digestive patterns of pancreas, liver and spleen; 1st and 3rd day.

(1) Pancreatic tissue digests most rapidly when made alkaline. Tissue acidity developed post mortem, or by the addition of acid to the digests retards the process. The more acid added, the slower the proteolysis. In the brei to which 75 c.c. N/5 HCl was added, practically no digestion occurs in ten days. The digestive pattern of this tissue is overwhelmingly of the trypsin-erepsin type.

(2) Under identical conditions the spleen digests most rapidly in those breis to which 25 and 50 c.c. N/5 HCl had been added. There is some digestion even where 75 c.c. N/5 HCl was added, and a pH of 2.96 attained. There is barely detectable digestion in the presence of 20 c.c. N/5 NaOH, and none at greater alkalinities. The spleen therefore gives a digestion pattern fundamentally different from that of the pancreas, and specifically fails to show proteolysis where the pancreas digests at maximum rate.

(3) The liver under the same conditions behaves like the spleen. There is considerable digestion at the highest acidity, while more than 20 c.c. N/5 NaOH inhibits proteolysis completely.

If no digestion takes place at reactions optimum for trypsin, we must conclude that either there is no trypsin present, or that the tissue proteins are resistant to trypsin. The following experiments therefore were made to determine whether liver and spleen proteins, under the conditions described, digest in the presence of small amounts of trypsin.

A 10 per cent suspension of the pancreatic tissue in water was added to spleen and liver breis in the amounts shown in the tables. To each digest was added 30 c.c.. N/5 NaOH to inhibit autolysis and to give a reaction favorable for tryptic activity.

It is evident that 1 c.c. of the suspension, corresponding to 0.1 gm. of the pancreas tissue, added to 50 gms. liver or spleen is quite sufficient to produce obvious digestion of the tissue proteins within 3.5 hours. One-tenth of this amount would certainly be recognized in less than 24 hours. The organ proteins are readily digested, and a very minute trace of the enzyme will disclose itself under the conditions of these experiments. If trypsin is present at all in liver or spleen, it must be in amounts below the threshold of detectability by the method used, and we submit that an undetectable trace is of doubtful metabolic significance.

While liver and spleen show no evidence of trypsin, they both demonstrate an abundance of the tissue proteases associated with autolysis. Both digest somewhat between a pH of 2.5 and 3, where trypsin is quite in-

active, and where pancreatic juice is also without proteolytic activity. This is sufficient evidence that Boldyreff's statement, "There are no endogenous ferments prepared by the cells themselves for the needs of general intra-cellular digestion (splitting and reconstruction of carbohydrates, fats, and proteins)," is incorrect. Liver and spleen contain an abundance of an enzyme group not present in pancreatic juice.

DISCUSSION

The evidence presented above we believe suffices to raise fundamental doubts as to the validity of Boldyreff's whole hypothesis. The literature is full of competent data too numerous to mention in detail here, which must be ignored if one accepts his theory. The extensive literature of autolysis negates it (7); Kathepsin is a well characterized protease not demonstrated in pancreatic juice (8); animals have been kept alive for long periods without their pancreatic gland, and without pancreatic feeding, provided insulin and lecithin or choline is supplied (9). One might well inquire what the evidence is upon which so far reaching a theory has been based, which at the same time appears so definitely counter to generally accepted experimental data.

In his previously published papers, in which the theory is first advanced, Boldyreff has been concerned with the phenomenon of rhythmicity along the alimentary tract. He demonstrates with a wealth of recorded observations a periodic activity which includes peristaltic waves and secretion of intestinal and pancreatic juice. The secretions are enzymatically active, although there is no food material in the tract. The juices secreted in the upper segments of the small intestine are practically all absorbed before the colon is reached, and the enzymes disappear. At least there appears to be no concentration of enzymes.

Rhythmic activity together with actual disappearance of juices and enzymes in the fasting intestine has led Boldyreff, therefore, to conclude absorption, distribution to the tissues, and the utilization of these enzymes in tissue metabolism. So far as we have been able to discover, that Author has not presented any further experimental evidence for the hypothesis. Instead, he has accepted reports from the older literature before there was adequate characterization of some of the enzymes, and before control and designation of the H ion level was possible. The fact of rhythmicity, and of disappearance of digestive factors from the non-digesting intestine does not in any way prove that these enzymes are lodged in the liver or spleen. Nor can we accept today, as authentic evidence of trypsin, such observations as that of Theobald Smith, made in 1894 (10), that sterile pieces of liver, spleen, and kidney liquefy gelatin. Yet this is the sort of evidence which Boldyreff cites to prove that these tissues do contain this enzyme. As a matter of fact, Smith himself did not draw this conclusion. He correctly regarded the liquefaction of gelatin by sterile tissue as enzymic digestion of the gelatin, and describes the action as "trypsin-like." We recognize today that Smith was dealing with the autolytic mechanism, in this interesting early observation. It is now well known that liver, spleen, or kidney made alkaline enough to completely inhibit autolysis will still digest peptone, gelatin, and casein. But the protease of the tissue which effects this cleavage will not attack the native tissue proteins. It is therefore not trypsin.

We are not questioning the fact that traces of the digestive enzymes are absorbed from the intestine from time to time, just as traces of undigested proteins are. Pepsin and trypsin have frequently been reported in the urine, and these reports are cited by Boldyreff as confirming his theory of metabolism. Actually, of course, trypsin in the urine is no evidence at all of trypsin in the liver. Nor is food allergy, which obviously depends on the absorption of specific food antigens from the intestine, any evidence that protein digestion is largely accomplished by pancreatic enzymes in the blood stream, as maintained by Oelgoetz.

SUMMARY

1. Under optimum conditions for tryptic activity, spleen and liver of the hog show no proteolysis.

2. Very small traces of trypsin added to these tissues under the same conditions give unequivocal evidence of proteolytic activity.

3. We have been unable therefore to find any evidence in support of the theory that trypsin is absorbed as such from the intestinal tract, to be distributed to and fixed by the tissues for their metabolic use.

4. Spleen and liver cells contain proteolytic enzymes not found in pancreatic juice and therefore not supplied them by absorption of that juice. It is logical to assume that they are produced by the tissue cells themselves, until definitely proven otherwise.

5. Any system of physiology, pathology, and therapy, based upon the assumption that pancreatic enzymes are regularly present in tissues such as liver and spleen, should be accepted with caution until some competent evidence is forthcoming to substantiate it.

The Influence of Bact. Coli and Its Products on the Motility of Strips of Excised Intestine*

By

LOUIS WEINSTEIN

and

LEO F. RETTGER

NEW HAVEN, CONNECTICUT

THE microorganisms which make up the so-called normal intestinal flora have quite generally been regarded as non-pathogenic so long as they confine their *habitat* to the intestine. Some have been found capable of setting up disease processes when they invade different parts of the body, as for instance, in *Bact. coli* cystitis, and *B. welchii* gangrene. However, it does not appear impossible that the bacteria normally present in the large intestine may at times account for organic and so-called functional diseases of the intestine itself. Brown (1925) believes that *Bact. coli* may play an etiological *rôle* in idiopathic ulcerative colitis. The bacteriological literature contains many references to the possible etiological significance of various members of the intestinal groups of bacteria in various pathological processes. We shall not attempt to review the entire literature here, but will cite several of the most recent publications which have appeared and which concern the organism upon which the main emphasis is placed in this paper.

Deak (1933) and Hassman and Herzman (1934) have shown that *Bact. coli* may be of etiologic significance in the enteric diseases of childhood. They believe that some strains of this organism are atypical, and have referred to them as "paracoli," because they do not ferment lactose. Some American investigators also have described paracoli strains, and have attributed to them an etiologic *rôle* in the summer diarrheas of children. Catel and Pollaske (1933), Silberstein and Singer (1924) and Rosenbaum and Chassel (1933) all worked with living and dead cultures of *Bact. coli*, and showed by various methods that this organism may play some part in the causation of intestinal disturbances. Adam (1927) and Goldschmidt (1933) demonstrated that *Bact. coli* can be toxic, and that when cultures are fed by mouth to animals they can set up an intestinal disturbance.

Hahsman and Scharfetter (1935) did considerable work with *Bact. coli* and studied its effect on the excised intestine of rabbits. They believe that filtrates of normal strains of *Baci. coli* do not affect the musculature of rabbits' intestine. Strains of *Bact. paracoli* obtained from children suffering from an intestinal disturbance always gave a definite response, usually increased peristalsis and tonus. Stronger concentrations of the filtrate paralyzed the peristalsis and tone. When the filtrates were allowed to act on the small intestine for a short time it was found that the reaction was reversible, but when allowed to act for a long time the reaction was irreversible.

Thus it can be seen, at least from the more recent literature, that the question of possible etiological relationships of the so-called normal intestinal bacteria is one of great importance and should be studied further. It is our purpose in this paper to present some findings regarding the action of a "normal" strain of *Bact. coli*, on excised strips of intestine.

EXPERIMENTAL

A strain of *Baci. coli* isolated from a normal human adult was used in all of the work reported here. Cultural and biochemical studies showed the organism to be of the *communior* type. The organism was grown in 2% Difco Bacto peptone water for twenty days; cultures so prepared constituted the material with which all of the tests reported here were carried out; this material was always distinctly alkaline. Studies were made with the whole culture, with the centrifuged supernatant, and with filtrates prepared from the culture, to determine their action on strips of excised intestine.

The cat was used as the experimental animal, since it could be procured easily at any time, involved little expense, and proved to be a fit subject for this type of experimentation.

The animals were sacrificed by stunning, and the strips of intestine used in the experiments were immediately removed and immersed in Ringer-Locke solution. They were stored (never more than two days) at refrigerator temperature before use. The strips of muscle were immersed in a bath of Ringer-Locke solution which was kept at 37° C and aerated by a stream of oxygen. The hooks and levers commonly used to obtain records of muscle contractions were attached to the strips and the movements recorded on a kymographic tracing moving at a standard rate of speed The muscle strips were held in the bath for at least thirty minutes in order to allow them to assume their normal rhythm. Definite but varying amounts of whole culture, centrifugate or filtrate, were then added to known volumes of the Ringer-Locke solution in which the strips were suspended. All of the test materials were heated to 37° C before they were placed in the bath. An uninoculated peptone mixture of the same composition as the culture, adjusted to the same pH and used in the same concentration, was always employed as a control.

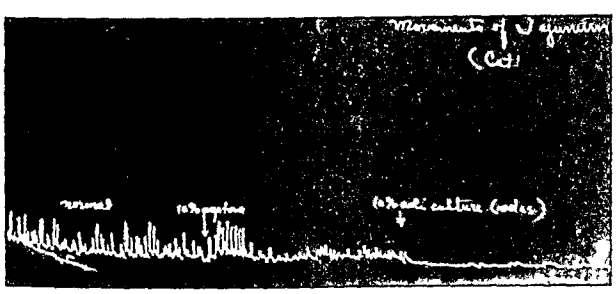
EFFECT OF BACT. COLI CULTURES ON THE MOTILITY OF VARIOUS PARTS OF THE INTESTINE

Different parts of the intestine were subjected to the action of the *Bact. coli* cultures in an attempt to determine whether or not they reacted differently in manner or degree.

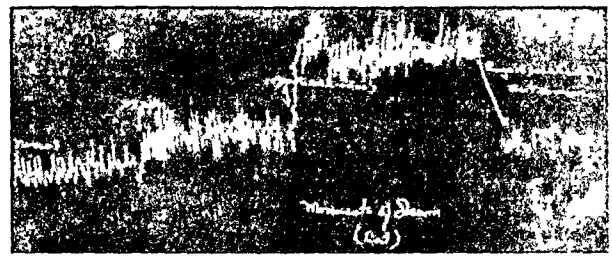
*Department of Bacteriology, Yale University.
Submitted January 29, 1936.

Effect on Duodenum and Jejunum. It was found very soon in the investigation that the optimum amount of whole culture which should be used to elicit a maximum reaction was 10 per cent of the total volume of the bath in which the intestine was immersed.

The *Bact. coli* cultures, when applied to strips of duodenum and jejunum brought about a paralysis of the intestinal musculature. There was a definite inhibition of the contractions and an almost complete loss of tonus. This reaction took place within 30 seconds to one minute after the beginning of exposure.



Graph 1. Effect of Bact. coli culture on Duodenum.



Uninoculated peptone water of the same composition as the medium in which the coli organisms were grown showed no effect when put into the bath containing strips of duodenum or jejunum, in the same concentration as the bacterial culture. (Graphs 1 and 2).

Effect on Ileum and Colon. The same cultures of *Bact. coli* (grown for twenty days in 2% peptone water medium), when added to a bath in which strips of ileum were suspended, gave a reaction which was directly opposite to the response elicited from the duodenum and jejunum. Within thirty seconds to one minute after the addition of the whole culture to the Ringer-Locke solution the strip of ileum responded with a very definite increase in tone and a speeding up of its contraction rate. A 2% solution of uninoculated peptone water gave no reaction except a slight rise in tone which was shown on numerous occasions to be of a very transitory nature.

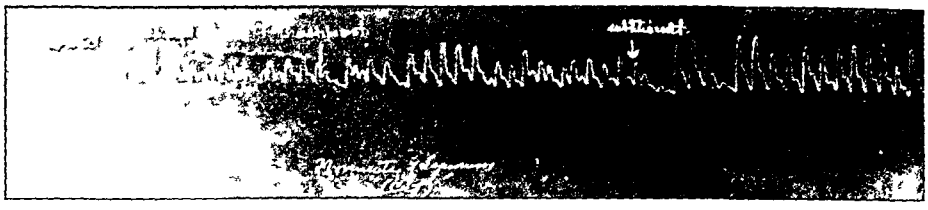
The *Bact. coli* culture, when allowed to act on strips of colon immersed in a Ringer-Locke solution, elicited the same type of response as from the ileum; but the increase in tone was much less than that of the ileum, and was only moderately higher than that brought about by the addition of sterile peptone solution. There was, however, quite a marked increase in the rate of contraction of the muscle strip. (Graphs 3 and 4). It was observed throughout this study that the colon reacted much more slowly to all of the applied agents, and that it required a relatively long time after first being put into the bath to become stabilized and give a normal contraction curve. Perhaps a much more

Graph 2. Effect of Bact. coli culture on Jejunum.

Graph 3. Effect of Bact. coli culture on Ileum. Reversibility of the Reaction.

definite response would have been elicited if we had used greater concentrations of culture; but this was deemed inadvisable because of the possibility of increasing the salt concentration to the point where it might induce a salt effect. While the results obtained with the strips of colon are very suggestive, no definite conclusions should be drawn from them.

Effect of Centrifuge Supernatant and Filtrate of Whole Culture. Attempts were made to demonstrate the presence of the substance (or substances) which was the active agent in the whole cultures of *Bact. coli*, in the centrifuge supernatant and filtrate of the culture. The cultures were centrifuged at high speed for about twenty minutes, and the supernatant fluid carefully pipetted off. This was then added to the Ringer-Locke solution in the bath in the same concentration as was the whole culture. In every instance the action of the supernatant fluid was essentially the same as that of the whole culture. It varied with the portion of the intestine exposed to it: that is, the ileum and colon were stimulated and the duodenum and jejunum depressed. The intensity of the reaction was in the same general range as that obtained with the whole culture, taking into account the normal variation in the reaction ability of different pieces of intestine from different animals.

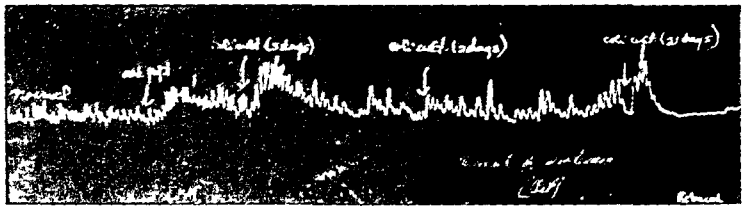


Chamberland (L3) filtrate of the whole culture was applied in the same way as the whole culture and supernatant. The active substance was found to be present in the filtrate also. (See Graph 8). The response of the strips of intestine was in general weaker, however, to the filtrate than it was to the whole culture or to the supernatant. The weaker action may be accounted for, at least in part, by the removal of some of the physiologically active substance from solution by the filter.

Graph 4. Effect of Bact. coli culture on colon.

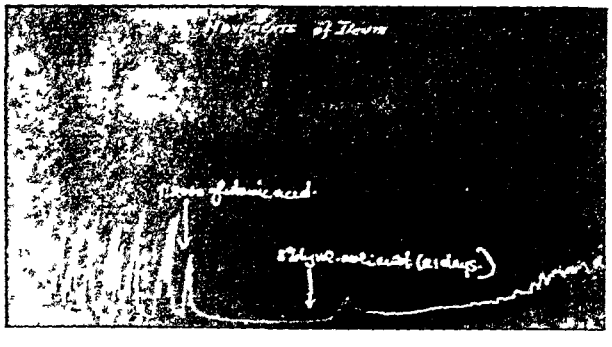
Influence of Length of Incubation of Cultures on Amount of Active Material Produced in Them. An attempt was made to determine how soon the active substance is produced in sufficient concentration to call forth the typical maximum response. For this purpose a 2% peptone medium was inoculated with *Bact. coli*

and incubated at 37° C. Portions were withdrawn at various intervals and their action on strips of intestine determined. Samples taken after two days' incubation were found to exert the opposite action on strips of duodenum from that obtained with twenty day old cultures; that is, two day old cultures caused a slight increase in tone and contraction rate. The same was true for portions of the culture taken out at the end of five days' incubation. The findings were essentially the same with the whole culture, the centrifuge supernatant and the filtrate. (See Graph 5 and 6). By the end of ten days' incubation the substance (or substances) which caused depression of the duodenum and jejunum, and excitation of the ileum and colon, was readily demonstrable, although the reactions elicited with this material were not in every instance of as great magnitude as those obtained with material from twenty-one day old cultures. (See Graphs 2 and 3).



Graph 5. Influence of Length of Incubation of Cultures on Amount of Active Material Produced in them.

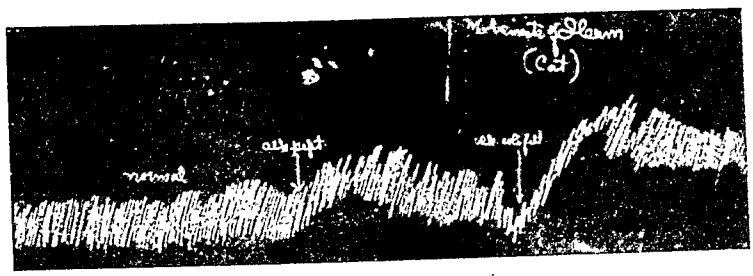
There are two possible explanations for the differences in the action of the young and older cultures. One is that the two substances are different in nature and that the first is destroyed during continued incubation at 37° C., possibly by the constantly increasing alkali that is formed in the culture. The other is that the two substances are one and the same in all instances, but that the reaction depends on the concentration of the active agent in the bacterial culture; in the two and five day old cultures the substance may be present in such small amounts as to bring about an excitatory response, whereas in the twenty-one day old culture its concentration is sufficient to exert a depressant action. This fact holds true for many of the exciting and depressing agents known to the pharmacologist; for example, alcohol in very small concentrations acts as a stimulant, while in greater amounts it exerts a marked depressant action.



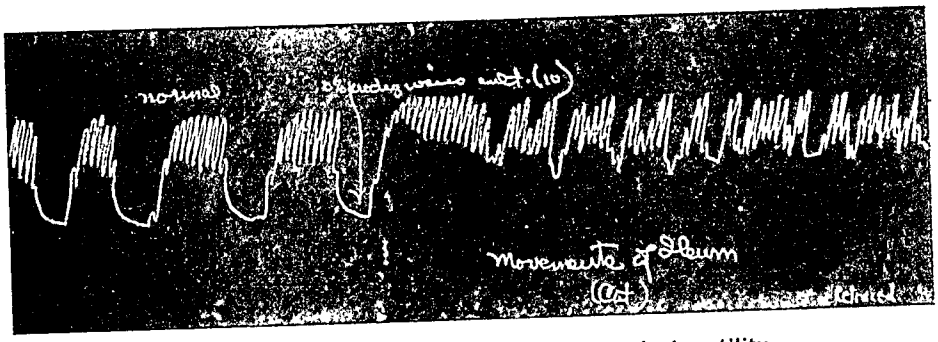
ABILITY OF THE INTESTINE TO RESUME NORMAL CONTRACTION AFTER TREATMENT

Experiments were conducted to determine whether the strips of intestine were capable of resuming normal contractions after they had been acted upon by the substances present in the coli cultures.

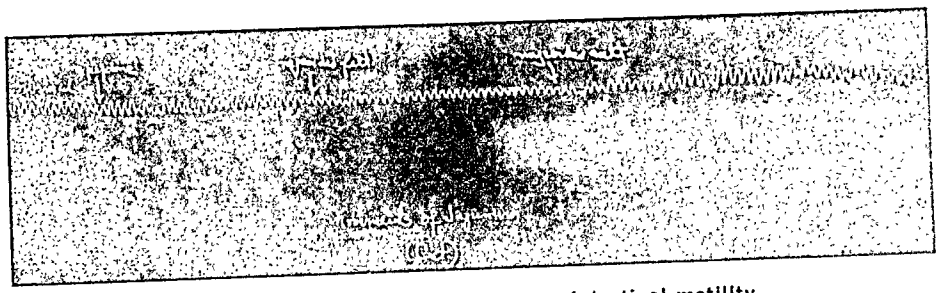
Strips of intestine were suspended in the Ringer-Locke solution and subjected to the action of *Bact coli* culture, supernatant and filtrate for varying periods of time. The bath was then emptied, new warm Ringer-Locke solution placed in it and the same strips suspended in the solution. It was found that strips of intestine from different parts of the tract could be subjected to the action of *Bact. coli* for periods ranging up to one-half hour without permanent damage to them. There was no apparent difference between the effects produced by the whole culture, the filtrate and the supernatant. (Graph 3).



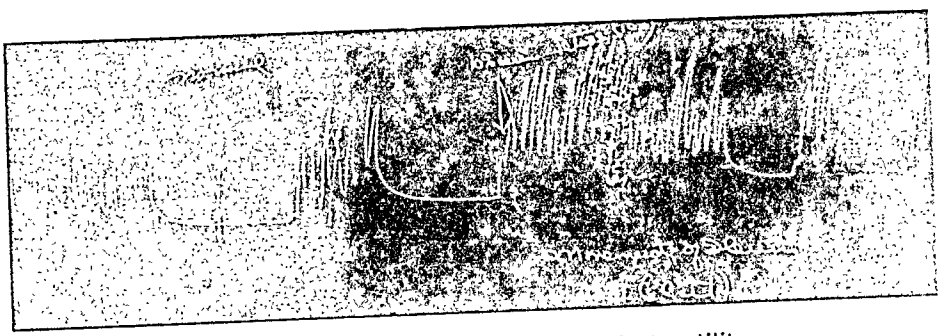
Graph 6. Influence of Length of Incubation of Cultures on Amount of Active Material Produced in them.



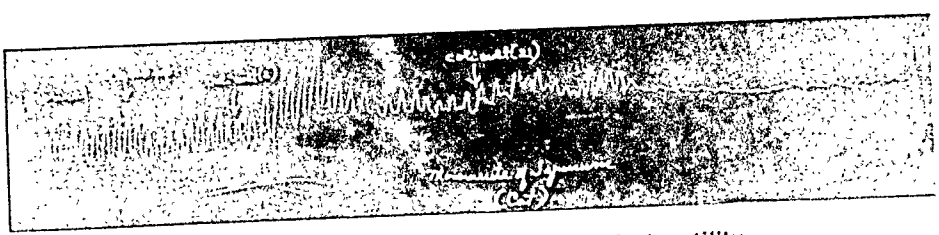
Graph 7. Specificity of the Reaction.



Specificity of the Reaction. In order to prove that the reaction to the products formed by *Bact. coli* was specific for this organism the following experiment was performed. Strips of intestine were subjected to the action of 1:1,000 glutamic acid, which had been shown before to paralyze intestinal movements, until all motility had disappeared and there was a loss in tone. When the reaction to the acid had been allowed to proceed for some time, coli culture was added. In every instance the culture tended to exert a neutralizing influence on the action of the glutamic acid. The experiments were conducted only with strips of ileum and jejunum, since all portions of the intestine were found to be paralyzed by the glutamic acid. The



Graph 8. Effect of Filtrate of whole culture.



Graph 9. Effect of S. marcescens on Intestinal motility.

Graph 10. Effect of B. mycoides on Intestinal motility.

Graph 11. Effect of B. cereus on Intestinal motility.

Graph 12. Effect of B. subtilis on Intestinal motility.

strips of ileum were made to undergo an increase in tone and a marked speeding up in their contraction rate by the addition of the *Bact. coli* after they had been acted upon by 1:1,000 glutamic acid. This experiment was repeated several times, with similar results; that is, the muscle tissue could be paralyzed by glutamic acid, revived by coli culture, paralyzed again with glutamic acid, and revived again by the coli culture. One phase of this reaction is recorded in Graph 7.

Effect of Cultures of Other Bacteria. In order to determine whether the property of eliciting the reactions described above is common to bacteria generally, or one that is specific for the colon bacillus, experiments were conducted with other bacteria, namely *S. marcescens* (prodigiosus) *B. subtilis, B. cereus* and *B. mycoides.* All were grown in 2 per cent peptone water at room temperature for from ten to twenty days, and added to the Ringer-Locke solution in the same proportion as were the *Bact. coli* cultures. No definite effects on the movements of the intestinal strips could be obtained with any of these organisms. Neither the whole cultures, their filtrates nor the centrifuge supernatants caused any definite response in the intestinal muscle. *S. marcescens* at times caused the intestinal muscle of the ileum and colon to undergo a slight increase in tone. This response, was, however, of a much lesser magnitude than that obtained with *Bact. coli* and could not be obtained with every strip of intestine used. Portions of the culture taken out at different periods of incubation showed that no reactive substance was present at any time. The results are shown in Graphs 9 to 12.

DISCUSSION

The problem of determining physiological responses to bacterial cultures is of necessity a very complicated one, because of the highly complex nature of the cultures. Attempts to pin down the reactive influence to one substance would seem rather futile, since the responsible material in the present study may be a purely metabolic product, an exotoxin or some endotoxic substance released from the cell by autolysis in a highly alkaline medium. That *Bact. coli* may produce amines and diamines, *e.g.* histamine, as was shown by Hanke and Koessler (1922), is accepted by bacteriologists generally. A definite specific exotoxin or endotoxin of *Bact. coli* has apparently not been demonstrated up to the present time. In this work we make no attempt to define the reactive substances, but merely wish to impress the reader with the fact that there is present in cultures of *Bact. coli* some substance (or substances) which exerts a definite effect on the motility of excised strips of intestine. This finding is in harmony with the observations of some of the investigators mentioned in the introduction.

Another point in these experiments which seems to us to be worthy of notice is the difference in the reactions elicited from the various portions of the intestine. The duodenum and jejunum gave responses directly opposite to those of the ileum and colon. Different chemical substances, histamine, adrenalin and various amino acids employed by Weinstein and Cowgill (unpublished) elicited the *same* response from *different* parts of the intestine. Three possible explanations for this difference in reaction suggest themselves to us. (1) The difference in reaction may be caused by a difference in the nervous elements in the walls of different parts of the intestine. (2) The *Bact. coli* culture may contain two different substances, one acting on the duodenum and jejunum to depress them, but having no effect on the ileum and colon, and the other acting on the ileum and colon in the stimulatory manner, but having no influence on the motility of the duodenum and jejunum. (3) The difference in effect may be due to a sensitizing effect brought about in the following manner: the duodenum and jejunum rarely harbor *Bact. coli,* while the ileum (especially the portion near the ileo-cecal valve) and the colon are in life in constant contact with *Bact. coli* and its products; the continued contact with this organism may cause the mucosa of the ileum and colon to become sensitized to products of *Bact. coli,* so that when these products are suddenly brought into contact with these tissues in high concentration a response quite different from that of non-sensitized tissue is brought about.

SUMMARY AND CONCLUSIONS

A substance (or substances) produced by *Bact. coli* in peptone water cultures which exerts a definite influence on the motility of excised strips of intestine has been demonstrated. This substance depresses the motility of the duodenum and jejunum and stimulates that of the ileum and colon. It is detected readily in cultures after ten to fourteen days' incubation.

The reactive material is present in the centrifuge supernatant and in filtrates of cultures of *Bact. coli.*

The reaction brought about by the culture material is reversible.

The reaction may be regarded as specific, since other bacteria, *S. marcescens, B. subtilis, B. cereus, and B. mycoides,* all of which are of non-intestinal origin, apparently do not produce substances which exert any definite action on the motility of the intestine.

Observations on Ulcerations Adjacent to Experimental Gastric Pouches in Dogs*†

By

ASHER WINKELSTEIN

NEW YORK, NEW YORK

WHILE studying the chemical phase of gastric secretion in a dog prepared with an abdominal wall "nerveless" gastric pouch†† a large area of ulceration was noted in the abdominal wall adjacent to the pouch orifice. The ulceration was 8 cms. long, 6 cms. wide and 3 cms. deep. During the oestrus, which occurred a short time later, this large ulcerated area healed completely. A similar healing of such ulcerations during oestrus had been noted on two other occasions in this dog and three times in another "nerveless" pouch dog. In this connection it is interesting to recall that the late Dr. Eugene Klein had already noticed and reported (1) that in four dogs there was an increase during lactation in the secretory activity and skin erosions about the "nerveless" chemical pouches. It was therefore thought important to make further observations and experiments on the relationship of the sexual cycle, the female sex hormones, and, certain ductless glands to such ulcerations appearing about gastric pouches.

In the female dog with the "nerveless" pouch, (Dog 1, "Alma"), following the healing of the abdominal wall ulceration during oestrus, renewed ulceration appeared in the latter part of the ensuing pregnancy. This area measured 4 by 3 cms.

Following the line of reasoning that the ovarian follicular hormone is chiefly responsible for the oestrus and was in some way associated with the healing during oestrus, and, a definite area of ulceration being established, during the next ten days, the follicular hormone "Theelin"**, 250 rat units b.i.d. was given subcutaneously. At the end of that period the ulceration was practically entirely healed. Five test meals of meat, 150 gms., and water, 200 ccs., averaged 4.9 ccs. secretion in 4 hours, 18 units free hydrochloric acid with a peptic activity of 2 mms. digestion in a Mett's tube.

The dog was then untreated during the next 3 weeks. A large area of ulceration measuring 8 by 5.5 cms. developed. A test meal during that period revealed 6.5 ccs. secretion, 30 free acid, and 2.5 mms. Mett's tube digestion.

The dog then gave birth to 9 puppies. During the lactation of 3 weeks the area of ulceration enlarged to 8.5 by 8 cms. A test meal during that period revealed only 0.85 ccs. secretion, 10 free acid and 2 mms. peptic activity.

Following this period of lactation, the ulceration healed completely in 4 weeks. Three test meals during that period averaged 3 ccs. secretion, 20 free acid, and 2 mms. peptic activity. This healed state persisted for the next two months. Test meals during that period averaged 3.1 ccs. secretion, 36 free acid, and 1 mm. Mett's tube digestion.

Again, following the line of reasoning that the anterior pituitary secretion is increased and "Theelin" absent during lactation, and, that the lactation period was associated with increased ulceration, the "anterior pituitary-like" hormone, "Antuitrin-S," 2 ccs. intramuscularly q.d., was administered for 10 days. After 4 days, an area of ulceration measuring 6 by 4.5 cms. appeared about the pouch. A test meal during that time revealed 5 ccs. secretion, 20 free acid and 2 mms. peptic activity.

The dog then went into the oestrus and in that period there was a complete healing again. A test meal showed 0.8 ccs. secretion, with 0.0 free acid and 0.0 pepsin. During the next 4 months there was no ulceration. Pregnancy did not occur after this oestrus.

The second dog studied was a male dog with a typical Pavlov pouch, (Dog 2, "Pedlo") viz. a fundus pouch connected with the main stomach by a submucosal bridge thereby retaining the nerve and blood supply of the main stomach and thus mirroring its activities, including the vagus and chemical phases of gastric secretion.

Two weeks after the institution of this pouch, a large area of ulceration appeared measuring 5.5 by 3 cms. which persisted 10 weeks. Test meals during that period averaged 21.5 ccs., 80 free acid, and digested 4 mms. of a Mett's tube.

"Theelin," 250 rat units b.i.d. subcutaneously, was then administered for 3 weeks. The lesion definitely diminished in size, and, at the end of 3 weeks, the lesion was completely healed. Test meals during these 3 weeks averaged 10 ccs. secretion, 80 free acid, and digested 3 mms. in a Mett's tube. The healing persisted throughout the next 2 weeks. There was then a minimal secretion of 0.2 ccs., 60 free acid, and 1 mm. Mett's tube digestion.

The next experiment, in view of the healed state, was to administer "Antuitrin-S," 2 ccs. q.d. intramuscularly for 2 weeks. Ulceration commenced to appear about the pouch orifice in 4 days and at the end of 2 weeks had reached the large size of 5.5 by 3 cms. There seemed to be a constant oozing of free hydrochloric acid from the pouch mucosa. There was no change in the area of ulceration for 2 weeks.

Again, "Theelin," 250 rat units b.i.d. was administered subcutaneously for 3 weeks. The ulceration gradually disappeared within these 3 weeks. Test meals during this period revealed 3.5 ccs. secretion, 100 free acid and a digestion of 2.5 mms. in a Mett tube.

No further ulceration was noted in the next 10 weeks. Test meals during this period averaged 11 ccs., 120 free acid, and a peptic digestion of 2.5 mms.

COMMENT

In the female dog with the "nerveless" pouch, oestrus apparently in some way was associated with the healing of the ulcerations about the pouch. Renewed ulceration appeared late in pregnancy and at-

*Presented at the 38th annual session of the American Gastro-Enterological Association Atlantic City, N. J., June 10-11, 1935.

†From the Pathology Laboratories, Mt. Sinai Hospital.

††This is a gastric fundus pouch invented by the late Dr. Eugene Klein in which the muscularis with Auerbach's plexus is stripped away and the mucous membrane pouch then implanted subcutaneously in the abdominal wall with a severance of the intra-abdominal blood and nerve supplies. This is the nearest approach to a completely nerveless pouch inasmuch as only Meissner's plexus is retained. The function of this plexus is unknown. Such a pouch secretes only in response to a chemical stimulus since the vagus phase has been completely abolished by the operative procedure.

(1) Klein, E.: *Arch. Surg.* 26:235 (Feb.) 1933.

**The "Theelin" and "Antuitrin-S" used in these experiments were obtained through the courtesy of the Research Dept. of Parke-Davis & Co.

tained its miximum during lactation. In the intervals between lactation and oestrus, in this dog at least, the ulceration may or may not appear. There does not seem to be a definite relationship between the secretory activity of the pouch and the amount of ulceration.

Experimentally, in this female dog, the ovarian follicular hormone ("Theelin") apparently promoted healing, or, at least, was in some manner associated with it. "Antuitrin-S" (the "anterior pituitary-like" hormone), on the other hand, seems to be associated with the production of ulceration. Here again the secretory studies did not demonstrate any definite relationship.

Considering the male dog with the Pawlow pouch, "Theelin" again was demonstrated to have a possible relationship to the healing and "Antuitrin-S" to increase ulceration in the abdominal wall contiguous to the pouch orifice. Here the large area of ulceration which appeared spontaneously before treatment was associated with a large amount of secretion from the pouch. Following "Theelin" administration, the quantity of secretion diminished markedly. However, an increase in secretion after "Antuitrin-S" was not noted.

The purpose of presenting these observations and experiments on the two dogs is to suggest the desirability of studying this problem systematically on a large scale. Furthermore, the possible relationship of such abdominal wall ulcerations about pouch orifices to internal ulcer of the mucous membranes of the stomach and duodenum should be considered. Of interest is the overwhelming predominance, in our experience, of human ulcer in the male sex.

DISCUSSION

DR. BORIS P. BABKIN (Montreal, Que.): The observations made by Dr. Winklestein on ulceration of tissue around the orifice of a gastric pouch are very interesting. The experiments on the relationship of the sexual cycle and some female sex hormones to such ulcerations are very suggestive, but the problem is too complicated to permit of drawing any definite conclusions.

Dr. Winklestein is very modest in his conclusions, presenting his observations and experiments with the chief aim of stimulating further work in this field; therefore, I should like to make only a few remarks and communicate to you the impression which I obtained in listening to this paper.

The figures of the volume of gastric secretion and its digestive power reported in Dr. Winklestein's work vary greatly and do not seem to stay always in a direct relation to the sexual cycle or to the administration of "Theelin" or "Antuitrin-S"; therefore, the formation of an ulcer around the orifice of the pouch seems to depend not on the amount of juice secreted or its digestive power during various periods.

It seems that the resistance to the peptic digestion of the skin, of the subcutaneous tissue, and muscles, is lowered during lactation on administration of "Antuitrin-S." It is true that during the lactation there was noted an increased secretory activity of the pouch. It must not be forgotten, however, that during the pregnancy, especially in its late stages, there is a continuous distension of the skin and its possible traumatization. With the onset of lactation and more profuse gastric secretion, this somewhat damaged tissue may undergo a much easier digestion than that of the normal tissue.

How complicated the problem of the inter-relations of endocrine glands and glands with external secretion is, may be shown by a few examples. According to Cushing, the undue secretion of the posterior pituitory lobe may be a factor in the causation of some gastro-intestinal disorders, including ulcers. One of Orbeli's pupils, on the other hand, showed that the administration of pituitrin to a dog with a gastric pouch produces a long, lasting depression of the gastric secretion, which could not be explained by vasoconstriction.

Another example: Dr. Winklestein noted during oestrus period or after administration of "Theelin," healing of the abdominal wall ulcers, and in some instances, although not always, a diminution of the gastric secretion. We have some occasional observations on female dogs with gastric pouches which definitely indicate that during oestrus the daily volume of the gastric secretion was almost doubled.

There is no need to try to resolve at the present time these and other controversial observations and facts. What is necessary now is a systematic study of the relations between the endocrine glands and the function of the gastro-intestinal tract. For certain reasons, and chiefly because the endocrinology itself is just emerging from a chaotic state, this was not done; therefore, Dr. Winklestein's work is valuable because it shows that such relationships exist and because it stimulates further investigations along these lines.

DR. A. C. IVY (Chicago, Ill.): Dr. Winklestein has made two very interesting and possible significant observations. One suggests that "Theelin" has an effect upon the healing processes; and the other is that "Theelin" depresses gastric secretion.

Now, in regard to the first indication, we know that "Theelin," or the sex hormones, are chemically related to growth promoting substances. For example: "Theelin" has a ring structure like the carcinogenic principle in coal tar products; so this is a bit of corollary evidence supporting the interpretation which he has suggested.

Now, in regard to the effect of "Theelin" on gastric secretion, the incidental observations that we have made in our laboratory on the effect of oestrus on gastric secretion are similar to those made by Dr. Babkin. In oestrus we generally observe the gastric secretory response to a meal to be augmented rather than depressed, and the same augmentation is generally true of gastric motility; however, that does not mean that the "Theelin" which we have available for use does not depress gastric secretion or even depress gastric motility, because "Theelin" may be different from the substance that is actually manufactured by the ovary in oestrus. Maybe the ovary is manufacturing something else. Maybe the situation is even more complex than that, as Dr. Babkin has suggested.

I am particularly interested in the possibility that "Theelin" may depress gastric secretion, and we at the present time have a number of dogs upon which we are making control secretory studies, with the intent later on of injecting some "Theelin" to see the effect of it on the gastric secretory response.

To my knowledge the effect of "Theelin" on gastric and intestinal motility has not been studied. It is a very important problem. It is also important to know the effect of "Theelin" and the various hormones associated with the female sex organs, on the gall bladder, because of the incidence of gall stones in pregnancy. There are reports in the literature which show that in some species, at least, in the latter part of pregnancy, the gall bladder does not evacuate normally; so that we have a very important field for investigation outlined, namely, the effect of the female sex hormones and associated hormones on the secretory and motor activity of various abdominal viscera.

DR. FRANKLIN HOLLANDER (New York City): Dr. Winklestein has asked me to mention to you several of my own observations on hypersecretion in dogs, provided with fundus pouches, during lactation.

The first of the series of observations was made quite accidentally. Subsequently it was possible to reproduce it under controlled conditions. Specifically the observation was this: We had occasion to prepare a fundus pouch of the Pavlov type on a dog in about the second week of pregnancy. In preparing this pouch we followed the usual practice in our laboratory of providing it with a sphincter at the mouth, just at the opening of the abdominal surface, by means of which sphincter it was possible to retain the secretion in the pouch for several hours at a time.

This modification of the usual technique was introduced for various experimental purposes and enabled us to measure the daily output of secretion with some accuracy. The animal was not used for experimentation for several weeks after the operation, although casual observations of the daily volume of secretion were made. During the four weeks between the preparation of the pouch and the dropping of the litter, the daily average output of gastric juice from this pouch was about 10 to 15 c.c. This was considered rather low for dogs that we had been preparing in our laboratory. The reason for the low value was not known at the time.

One morning when the animal man went to feed the dog in its kennel, a litter of pups was found. We were not sure, I may say, whether the animal was pregnant or not, at the time of the operation, because of various extenuating circumstances. The animal had ripped the dressing from off the abdomen, and although there had been absolutely no erosion around the pouch on the previous day, the erosion noticed on this morning was very extensive. It covered an area of more than the size of half a dollar, and was quite deep, and we were surprised to find that the pouch contained a very large amount of highly acid secretion.

We followed the acid output very carefully thereafter and observed that during three to four weeks of lactation the average rate of acid secretion was about 150 c.c. a day. On some days it rose as high as 200 or 250 c.c., and was continuous practically throughout the twenty-four-hour period. This, mind you, was in contrast with the situation previous to dropping of the pups, where we had an average daily output of no more than 15 c.c. The acidity both before and after this critical day was on the average the same. We were getting very pure gastric secretion, and the acidity was in the neighborhood of 150 to 160 clinical units, that is, 150 to 160 millimolar concentration.

This high rate of secretion continued during the three to four weeks of lactation. Thereafter the pups were weaned progressively and with this weaning we found a very marked falling off in secretion. By the end of the sixth week, the rate of secretion had fallen to about 30 c.c. per day on the average and dropped continuously thereafter. The animal was lost by an accident during the seventh week so it was not possible to continue the observations any further.

Subsequently we tried to reproduce this under more controlled conditions. Two pouch animals that had been prepared some time before, were mated. In both cases we got the hypersecretion, but in neither case was the increase in secretion nearly as high as that which had been observed in the first. Actually the average increase was no more than two or threefold, whereas in the first animal the average increase was tenfold or greater. Similar observations have been made by Dr. Eugene Klein and Dr. Ivy, but in neither case did the magnitude of the hypersecretion approach ten to twentyfold, as in our first dog. Thus we have in these findings further coroboration of Dr. Winkelstein's major thesis regarding the functional interrelations of the glands of internal and of external secretion. There can be no doubt of the importance of these interrelations and of the need for their thoroughgoing physiological investigation.

SECTION III—*Nutrition*

Ketosis as Measured by the Ketonemia Following Fat Ingestion by Obese and Non-Obese Patients*

By

EDMUND L. KEENEY, M.D.

JAMES W. SHERRIL, M.D.

and

EATON M. MacKAY, M.D.

LA JOLLA, CALIFORNIA

INTRODUCTION

THE ketone or "acetone" bodies in the blood are apparently end products of incompletely oxidized fatty acids. These substances are acetoacetic acid, B-hydroxybutyric acid and acetone in order of formation. They occur in the blood at a low level under normal conditions and in the fed subject seldom exceed 1 mg. in 100 c.c. The term "ketosis" is used to imply an abnormal accumulation of the ketone bodies in the blood (ketonemia), and an excessive excretion of the same substances in the urine (ketonuria). The determination of the blood ketones is a somewhat difficult and tedious procedure and has been but little applied to general clinical studies. As a result of this, ketonuria alone generally has been studied. There is reason to believe from the data of Allen, Stillman and

*From The Scripps Metabolic Clinic.
Submitted January 27, 1936.

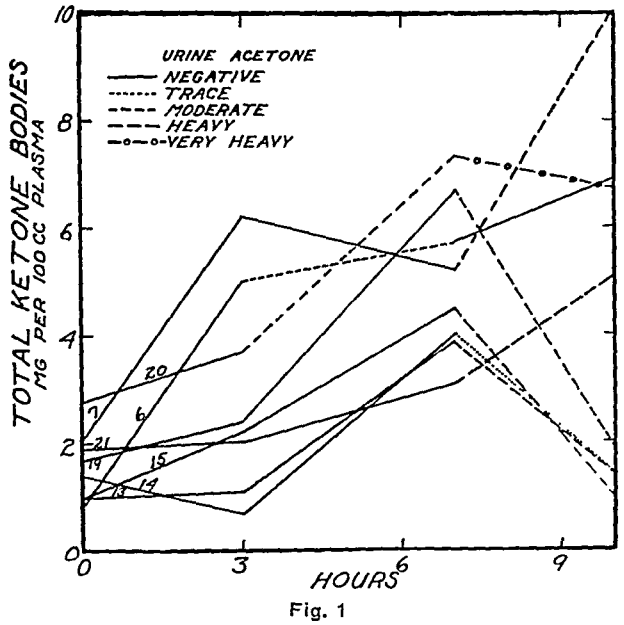

Fig. 1

Fitz (1) that this may be a poor measure of the degree of ketosis. It seemed probable that some insight might be gained into a possible abnormality in the fat metabolism of obese individuals by a study of the degree of ketonemia under certain controlled conditions.

METHODS

Fat meals were administered to fasting patients and the total ketone bodies of the blood determined at definite intervals thereafter. We were unable to control the pre-experimental diet in our patients but there is no indication that it influenced the results in our experiments. (See discussion). Five patients (Nos. 1, 2, 3, 4, 17) had been on a low fat, low caloric diet. Six of the group (Nos. 11, 12, 16, 17, 19, 20) had been eating their natural diet at home while the rest had been on the regular general diet at this Clinic. After partaking of their usual evening meal of the preceding day, no food or medication was allowed until the observations were completed.

At 6 A. M. a blood sample was drawn for a ketone body determination. Immediately thereafter 150 c.c. of 36-40% cream per square meter of body surface were given with a small amount of water. Body surface was calculated from the formula of DuBois (2) using the observed body weight. Blood samples (20 c.c.) were taken in all of the experiments 3 and 7 hours *post cibum* and in the later experiments 10 hours after the cream was administered. The total ketone bodies were determined on the serum by Van Slyke's method (3). Urine was collected in some experiments over the periods between each blood sample, from 0-3 hours, 3-7 hours and 7-10 hours, and examined for acetone and acetoacetic acid by Rotheras' and Gerhardt's tests respectively.

Most of the patients had been in bed before the test. During the first experiments some of the patients were allowed to walk about the corridors or sit in chairs, but we noticed Gemmill's (4) report that subjects on a low carbohydrate diet show a rise in blood acetone following exercise, and the majority of the experiments were carried out under approximately basal conditions.

EXPERIMENTAL MATERIAL

The patients who were submitted to our "fat metabolism test" were selected, except for certain minor details, only insofar as they were obese or not obese and that they had no other obvious metabolic disorder. In the administration of a fat meal, one becomes directly interested in the patient's ability to digest and absorb fat. Patients with clinical symptoms or laboratory findings suggestive of pancreatic, biliary or gastro-intestinal disease were excluded from our summary of data on obese and non-obese subjects. None of the subjects complained of untoward symptoms during the experiment.

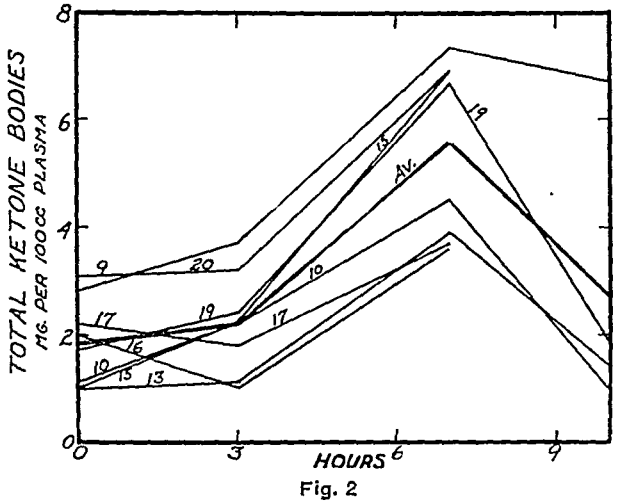

Fig. 2

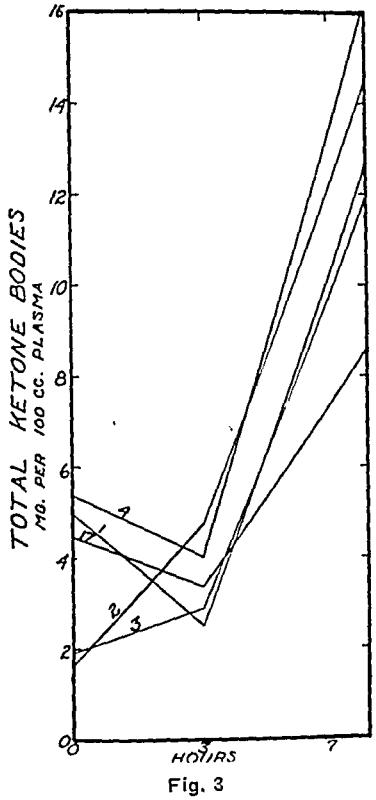

Fig. 3

RELATION OF KETONURIA TO THE DEGREE OF KETONEMIA

In the patients (Fig. 1) in which urine specimens were collected and tested all tests for diacetic acid except two were negative. Acetone was of course also present in these two specimens, as well as others. Figure 1 indicates the relation of the ketonuria to the

serum ketone concentration. In only one experiment did an acetonuria appear in the urine collected at 3 hours *post cibum*. In all of the other patients acetone appeared in the 3-7 hour urine and was still present in the 7-10 hour urine.

We have already noted that the relation between blood and urine ketones has not been studied and the

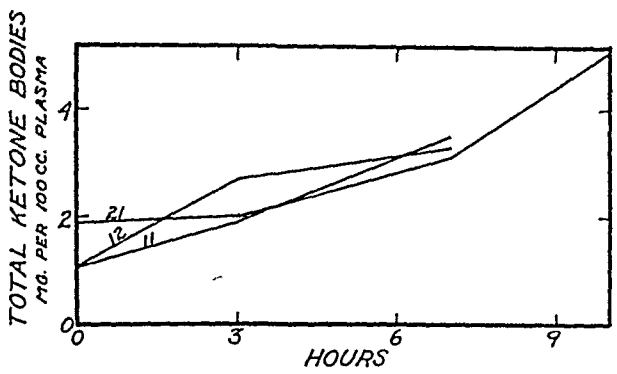

Fig. 4

data of Allen, *et al* (1) indicate a peculiar lack of association between the two. In no patient did acetonuria occur unless the serum ketone level was observed above 3.1 mg. per 100 c.c.. The apparent average blood ketone level at the time of the initial appearance of the acetonuria was for all patients 4.5 mg. per cent. The existence of a renal threshold is of course implied. At levels of the blood ketones higher than 4 mg. per 100 c.c. acetonuria was continuously observed. In the three patients with an acetonuria between the 7th and 10th hours while the blood ketones were falling to low levels it is probable that the acetone in the urine was excreted while the serum ketone concentration was above 3 mg. per cent.

RESULTS IN NON-OBESE PATIENTS

The eight subjects in the non-obese group ranged in age from 26 to 66 years. The curves of the plasma acetone bodies for this group forms Figure 2. It will be observed that the average fasting blood ketone level is 1.86 mgm., which is in accord with the figures found by Marriott (5). At the end of 3 hours, the ketone bodies rose but little. However, at the end of 7 hours there is an average increase of 3.8 mgm. per 100 c.c., with a maximum rise in one case of 5.8 mgm. The only drop below the blood fasting level occurred in two patients (Nos. 16 and 17) after three hours. At the end of 10 hours, in nearly every case, the curves were approaching their fasting levels.

RESULTS IN OBESE PATIENTS

These subjects represented a group of individuals ranging in age from 28 to 52 years. In all patients studied in this group the fat was generally distributed. Four of the group were from 40 to 100 lbs. over their normal standard weights. One had dieted rigidly and was at the time of the experiment only 20 lbs. overweight. Previous to the experiments, all the patients were on a low fat, low calorie diet.

The blood ketone curves of the obese patients are depicted graphically in Figure 3. One will readily recognize the great difference in the contour of the curves representing the majority of the obese from those which are representative of normal subjects (Fig. 2). In the case of the obese, the average fasting blood ketone level is 3.6 mgm., about twice the fasting level of the average normal. As in the case of the normals, there is no considerable change after 3 hours. At the end of 7 hours there is an increase of 9.1 mgm., per 100 c.c. which is nearly 3 times that obtained for

normals. In 3 of the patients, (Nos. 1, 4, 17), there was a fall below the fasting level after 3 hours *post cibum*. The maximum rises were respectively 13.1 mgms. and 4.1 mgm.

MISCELLANEOUS OBSERVATIONS

Observations were made on patients 6, 7 and 14 without the idea of including them in our normal or obese groups. In 6 and 7 the ketonemia was a little higher (Fig. 1) than the normals. Patient 6 gave symptoms suggestive of an endocrine disorder and patient 7 had a diagnosis of gall bladder disease. Patient 14 was a typical case in clinical appearance, of acromegaly although the usual laboratory tests were all normal. The degree of ketonemia following fat ingestion in this patient was no greater than in the normals.

We have considered three obese patients, (Nos. 11, 12 and 21) on whom the degree of ketonemia was within the normal range, separately (Fig. 4). Patient 12 had had diarrhea for 2 weeks prior to the test as a toxic manifestation of digitalization and it is possible that this hindered the absorption of the fat meal. On patient 11 the blood glucose determinations made concomitantly with those for acetone were likewise low, and we can offer no fitting explanation of either finding. Patient 21 had gained weight steadily since an ovarian operation 9 years ago, and we can only speculate as to the relation of the low acetone curve to the apparent glanular dysfunction.

DISCUSSION

It has been shown quite definitely that the ketone bodies are produced in the liver (6). Are the differences we have found between non-obese and obese subjects due to a higher fat content of the liver in the latter group? At autopsy, obese subjects generally have fatty livers but as a rule they have been suffering from some disease and probably had been given an insufficient diet preceding death which might easily be the cause of a fatty liver. We are unaware of any direct evidence on the question for man but Foster (7) has demonstrated extremely fatty livers in the remarkable obesity which follows injuries to the brain in the region of the hypophsis of the rat. Furthermore, these livers presented an exception to the usual generalization that, when the liver fat is high, the glycogen is low and *vice versa* for, with the high fat, they contained more glycogen than the livers of non-obese rats. This is important for such conditions would of necessity exist in the livers of obese humans if their livers had at all times a high fat content. If these subjects naturally have fatty livers this might account for our results as Duel, *et al* (8) have found that the ketonuria developed in the rat is greater when any amount of fat has been deposited in their liver.

If obese subjects developed a ketosis more readily than other patients, this might easily explain our results but the belief is generally held that, in obesity, the onset or severity of the ketosis of starvation is no different from that in non-obese individuals. In the absence of direct evidence upon the subject, it would seem reasonable to suppose that the ketosis in the obese, during fasting or on a high fat diet, would be greater than in the normal simply because of the nature of their metabolic mixture due to the excessive fat deposits available for oxidation. Twenty years ago Folin and Denis (9) came to the conclusion that "obesity is not a predisposing or contributing factor in the onset of the acidosis of starvation" from a study of two obese subjects and one of these developed an unusually high degree of ketonuria. Now Deuel and Gulick (10) have recently concluded that "obesity is not a predisposing cause of acidosis," but, if we examine their data on male subjects, we find two whose heights and weights indicate that they are obese. The average of the 9 fasts on these two obese subjects in comparison with the average of 13 fasts on their 3 none obese subjects, shows a ketonuria at least twice as great in the obese, commencing even on the first day. It is possible that this is the explanation of the difference in the ketonemia of obese and non-obese subjects which we have observed.

There are obviously many factors involved in the degree of ketonemia which occurs after the ingestion of fat. The occurrence of the usual non-obese results in obese subjects and *vice versa* indicates that "fat tolerance tests," as measured by the ketonemia following fat ingestion, have little diagnostic significance and at most are of physiological interest in the study of obesity.

Goldzieher, *et al* (11) have proposed a test somewhat like the one used in the present study for diagnostic purposes in disease of the anterior pituitary. Although we made no direct examination of their method, such comparison as is possible between their work and this investigation would not seem to lend support to their results. Goldzieher and his co-workers interpreted a rise in the blood acetone bodies, one and two hours following the ingestion of fat after an overnight fast, as normal. We frequently failed to obtain any degree of ketonemia within even three hours after heavy cream alone and after the addition of more carbohydrate (heavy cream contains considerable carbohydrate) to the cream we have never found any increase in the blood ketones. The investigators in question diluted the cream fed with an equal volume of milk and fed still more carbohydrate in the form of two slices of toast with an ounce of butter. A drop in the blood ketones such as they postulate after a fatty meal in persons with disease of the anterior pituitary occurred here when there was no evidence of pituitary disease, (Table I and Figures).

SUMMARY

The degree of ketonemia is a better measure of the degree of ketosis than is the ketonuria.

In obese patients the ketonemia following a fat meal is generally higher than in non-obese patients. This may be due to the easier development of ketosis in obese subjects although this view is not supported by the conclusions in the literature.

Some obese patients develop no more ketonemia following a fat meal than do the majority of non-obese patients and some normals develop a ketonemia of the obese type. Reasons for this are discussed.

The evidence at the present time does not support the view that fat tolerance tests may aid in the diagnosis of pituitary disease.

Is Gastric Secretion or Digestion Impaired by a Mixture of Carbohydrate and Protein in the Diet?*

SAMUEL S. FELS

PHILADELPHIA, PENNSYLVANIA

EVERY era and every generation have seen "healers" prey upon the gullibility of mankind, for in nothing is the human credulousness so unbounded as in matters of health and disease. These mountebanks, to paraphrase Pliny (a), traffic with our lives to make a name for themselves through some novelty. Moreover, this was probably never truer than in our own time. Progress in medical science and invention has sharpened the wits of Man, yet popular medicine remains ridiculous because its dicta make such easy prey of otherwise intelligent people. The innate horror of sickness and death that in the Stone Age created the medicine man, that later brought the best people of France to a Mesmer, or sold the metallic tractors of an Elisha Perkins (b) to the founders of our own nation, today supports in kingly fashion the lecture tour of one diet faddist or another, because emotionally we are still walking with Cro-Magnon man.

These various fads may have no more foundation in science than the cabbage and gibberish of a Cato the Censor (c), or the abracadabra of a Serenus Samonicus (d); nevertheless, scientific medicine ought not to expect to outlaw them by the puissance of its established authority or by a barrage of invective. The latter is too like professional bigotry, and the former has too often been directed against genuinely outstanding medical figures to be entirely free from suspicion. From the professional persecution of Vesalius to the Academic resentment against Pasteur, medical history is not wanting in injustices of our body scientific. It remains, therefore, for Medicine to examine these fads in proper investigations and to establish or to deny their claims through legitimate studies.

A diet fad today enjoying a great vogue is founded upon the idea that the stomach secretions are unfavorably affected by a mixed carbohydrate-and-protein diet. It is implicit that such a diet would produce abnormal digestion and subsequent harm to the economy. The

*Mr. Samuel S. Fels has not only made the grant under which the studies were originated and carried through, but at weekly conferences contributed much to the actual work.
Submitted January 6, 1936.

(a) Pliny the Elder, Gaius Plinius Secundus (23-79 A. D.), in his "Natural History," decrying some of the medical practices of the period, writes: "Nec dubi e omnes istos fama nouitate aliqua aucupantes animas statim nostras negocinri." (There is no doubt that those who seek to be in vogue by some novelty or other, acquire it at the expense of our lives). Caii Plinii Secundi: Naturalis Historiae Libra XXIX.

(b) Elisha Perkins, born in 1741, was a Connecticut physician who devised two metal rods (Perkins Patent Tractors) which would draw off disease from the body. He numbered among his purchasers some of the contemporary leaders of the country. "Fads and Quackery in Healing," by Morris Fishbein. Blue Ribbon Book, Inc., N. Y., pp. 9-12, 1932.

(c) Cato the Censor or the Elder (234-149 B. C.). In his book, "De Agricultura," prescribed cabbage, the favorite vegetable of the Pythagoreans, for all ills. He ordered it internally, both raw and cooked, and as a poultice for sores; he declared it would cure even cancer and he injected its juice into sinuses and fistulae by means of a syringe composed of a bladder tied to a reed. Medical History From Earliest Times. Ed. Dawson Withington, Scientific Press, London, p. 71, 1894.

(d) "With the passing of Galen at the end of the second century, the thread of rational medicine snaps. Medicine now strips at a ghostly loom, producing charms and amulets, and the dozen of the age is the Abracadabra. The book De Medicina Praecepta which wound out to fifteen hundred hexameters entangled the profession and public alike. Classics which should have been immortal have perished, while the rubbish of Serenus Samonicus has survived, for its formulae were repeated in countless incantations and the sick wore the magic word—Serenus Samonicus explained that abracadabra must be written out on the first line, and a letter dropped with each succeeding line thus forcing the demon of the disease gradually to release its grip upon its victim." Victor Robinson, The Story of Medicine, Tudor Publishing Co., N. Y., pp. 193-194. See also Quinti Sereni Samonici De Medicina Praecepta Salubertima

whole idea originates, obviously, in the isolated scientific fact that proteins require a relatively high gastric acidity for initial digestion, while carbohydrates need an alkaline medium. Out of this has been built a

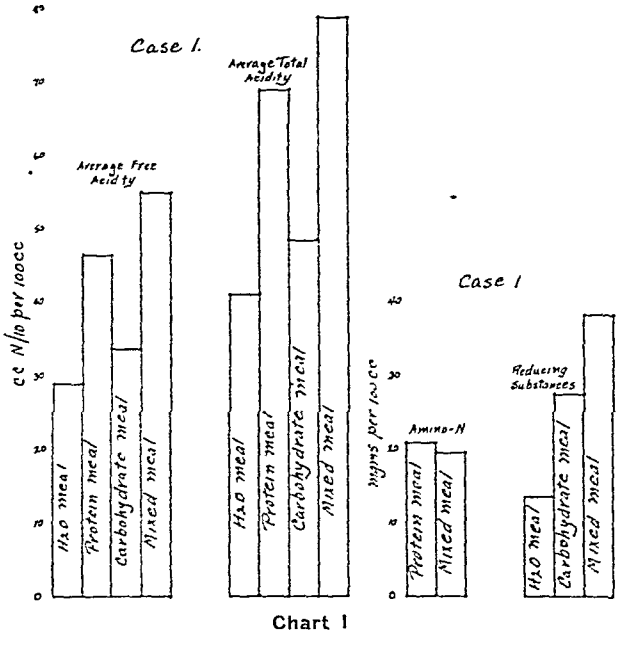

Chart I

series of "do's and don'ts" which is presumed to separate the groups of foodstuffs.

Rehfuss (1), realizing the importance of investigating the claims of such a diet cure, recently published, for fifty cases of chronic illness, the gastric acid response to a protein, a carbohydrate, and a mixed meal. He was unable to detect any notable difference in the average acid response to any of these meals. Independently, about two years ago, we began a detailed study of the gastric response to similar meals in a group of healthy individuals in order to test the validity of forbidding such mixtures in the diet. We

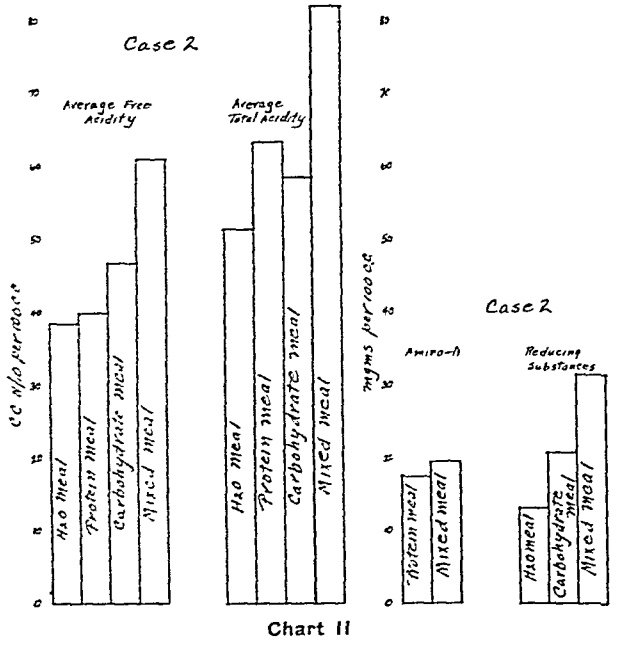

Chart II

felt that because of the variations possible in test-meal studies (the result, no doubt, of the fact that such studies now represent secretion concentrations of *unit volume* and *not unit time)* it would be better to obtain the average figures for each type of test meal through repeated studies with the meal on a small group of patients than to depend upon single observations on a large group. Five cases were so studied: four with normal secretory responses and one with a gastric anacidity. The fractional method of gastric analysis was employed throughout. The test-meals consisted of 300 c.c. of distilled water alone; of 9 grams of egg albumen (Merck); of 15 grams of soluble starch (Merck); and, finally, of a mixture of the two dissolved in the always constant volume of 300 c.c. of distilled water. Our studies included a titration of free hydrochloric acid to dimethyamidoazobenzol (Topfer) and a titration of total acid to phenolphthalein. We also made determinations of the hydrogen ion concentration with the quinhydrone electrode; of total

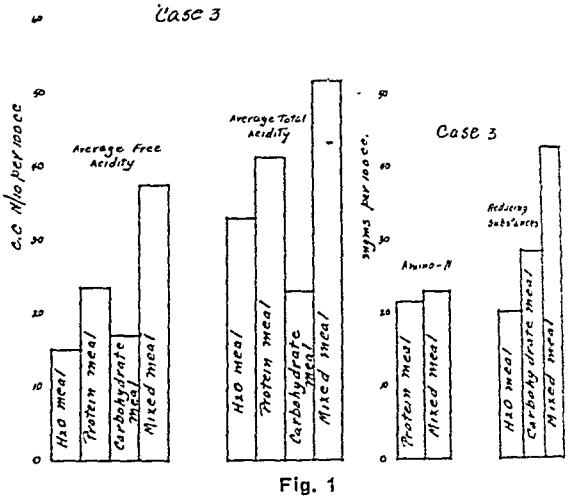

Fig. 1

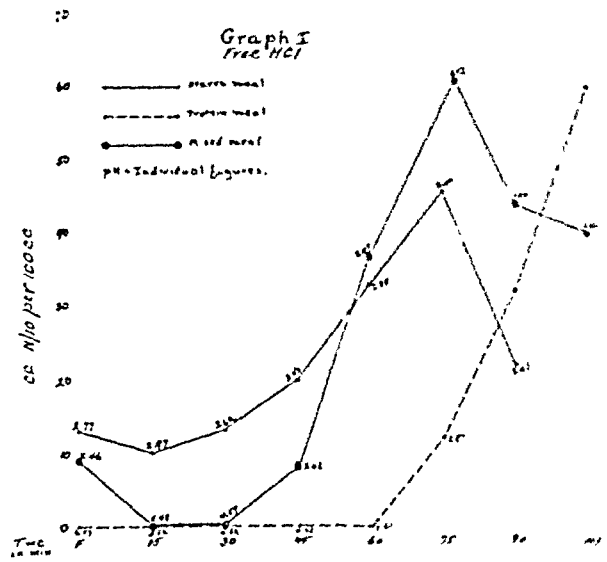
chlorides by a modification by Wilson and Ball (2) of the Van Slyke method; of pepsin by a slight modification of the method of Polland and Bloomfield (3). These data upon analysis help us to answer the problem of the interference with the proper gastric secretion by food mixtures. We also tried to determine whether the intragastric decomposition of either carbohydrate or protein was retarded by their mixture in the diet. Therefore, we investigated the change in concentration of reducing substances in the gastric samples, after the starch and mixed meals, by the Hagedorn-Jensen method (4) for blood-sugar. We determined protein cleavage by the amino-nitrogen concentration, with the Van Slyke (5) amino-nitrogen apparatus, following the protein and mixed meals. Numerous studies were done simultaneously on the blood, urine, and saliva, in order to study the secondary general effects of gastric secretion and digestion, and the motor effects were subsequently investigated by means of the X-ray. We are limiting ourselves, however, at this time to the gastric findings only.

AUTHORS' STUDY



This report is based upon more than 6,000 determinations made on over 900 gastric specimens obtained

from five patients in successive studies with the meals outlined above.

Chart I gives the average of all the figures obtained for each gastric constituent for each of the test-meals employed. In determining these averages, the fasting values have been eliminated from the calculations because they were not directly concerned with the response to the various meals, and we felt that by eliminating them we could obtain a truer figure of the response.

We included the plain-water meal in our studies in order to show that water alone produces an adequate secretory response. That water may do this in man, has been pointed out by Ivy (6) and has recently been reiterated by us (7). Particularly interesting is the fact that the carbohydrate meal alone may call forth even a greater secretion of gastric acid than the water alone. In one instance, Case 2, the average free acidity of the carbohydrate-water meal was more than 20% greater than that provoked by the pure water. In Case 2 it also appears that the average response in free acidity was even greater than that obtained with the protein meal. This, however, we believe is more apparent than real, because if we remember the acid-combining power of the protein, we can thereby account for some of the free acid in the total acid figure. It will be noted that in every instance the average acid response obtained with the mixed meal was higher than that obtained from the protein meal alone. The average total chloride figures generally followed the acid curves. The fact that we occasionally obtained lower pH average readings with the water and water-carbohydrate meals than with the protein and mixed meals, in spite of the higher titratable acidity provoked by the latter, is not surprising when we consider the combining factor of the proteins present and the increased buffer action. In most cases the average pepsin concentration was higher with the water-carbohydrate meal than when protein was present.

More striking still, from the standpoint of our thesis, are the individual acid curves. Graph I illustrates this point. The protein in the meal, combining with the available free acid during the earlier periods of digestion, permits the reaction of the gastric contents to remain more favorable for amylolytic action

Graph 1. Curves of free acidity obtained with carbohydrates, with protein, and with mixed meal, illustrating how the presence of protein in the diet would actually favor continued carbohydrate digestion in the stomach. This is evidenced not only by the prolongation of the period of low titratable acidity following the ingestion of food, but also by the more favorable hydrogen ion concentration that would more likely permit continued amylolytic activity.

during a longer time than when carbohydrate alone is ingested. *It appears, therefore, that continued salivary digestion in the stomach would be favored rather than hindered by the admixture of carbohydrate and protein.* It is interesting to note that the highest average concentration of reducing substances for the carbohydrate meals (46.12 mgs. per 100 c.c.) in the gastric contents was obtained in the anacid case. This is, of course, explicable on the basis of better and more continued salivary action in the absence of all gastric hydrochloric acid. (We feel that the rest of the material on the anacid case is irrelevent to the main point under discussion here and have, therefore, omitted it).

The average amino-nitrogen concentration was as great in the meals containing a mixture of carbohydrate and protein as in those containing protein alone,

while the reducing substances in all the cases showed a higher concentration in the mixed meal than in the straight starch meal, again emphasizing the greater carbohydrate splitting in the stomach in the presence of protein. These findings show clearly that neither protein nor carbohydrate splitting was impaired in the slightest when ingested in combination.

DISCUSSION

Since our experimental data show clearly that there is impairment neither of gastric secretion nor of gastric digestion following the ingestion of a mixture of carbohydrate and protein, we may still ask for an explanation of the many "cures" reported for a diet in

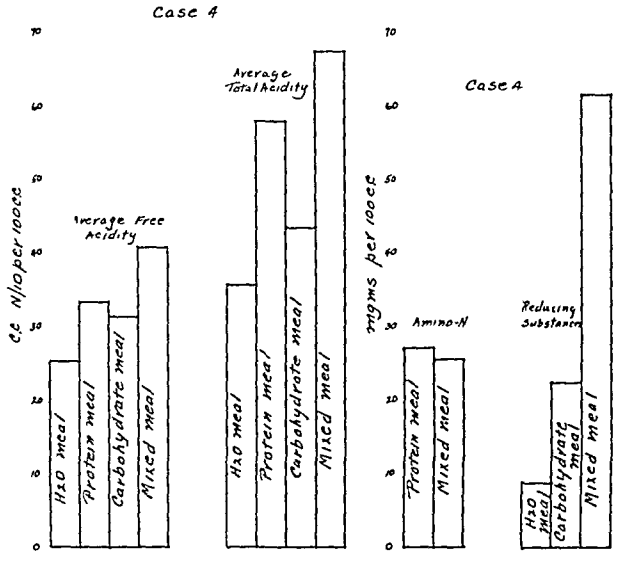

Fig. 2

which these food groups have supposedly been separated. The answer lies very probably in the natural improvement of any diet over the original unintelligent eating habits of a great many of us. These habits, characterized as they are by gluttony; an excessive consumption of highly concentrated foods, especially carbohydrates; and a failure to exercise properly result in an atonicity of skeletal and intestinal musculature; excessive fat deposits; flatulence; and constipation. If we now replace the highly concentrated starches almost entirely by the 3% and 5% starch vegetables and the 5% and 10% fruits, satiation will be achieved with a much smaller caloric intake. In this way, the pabulum for the fermentative organisms in the bowel will be diminished, and their growth will be discouraged, with a consequent reduction in flatulence. With the additional bulk in the diet, the atonic bowel will be encouraged to better bowel function without the use of laxatives, a weight loss will follow the smaller caloric intake, and as a result of all these an inevitable improvement in the condition of the patient.

Such an explanation for a special therapy is embarrassingly simple and would, naturally be completely unimpressive to an Age so thoroughly complex. Therefore, the talk is of "impaired gastric secretion," and "gastric digestion," etc., which is highly significant, but quite inappropiate phraseology. One must recognize too, that very harmful results may follow such a diet in patients with gastritis, duodenitis, an irritable colon, or a true colitis—results which will, of course, remain unpublicised.

SUMMARY AND CONCLUSIONS

Five people, free of any organic gastro-intestinal disease, were studied by repeated fractional gastric analysis following meals of distilled water, a pure carbohydrate, a pure protein, and mixtures of the two. Four had a normal gastric acid response and one was an achlorhydric. The studies were done in order to test the validity of the claims made that mixtures of protein and carbohydrate interfere with proper gastric digestion. The gastric secretory studies included the usual titration of acidity to Topfer's and to phenolphthalein, hydrogen ion determinations, total chlorides, and quantitative pepsin. Gastric digestion was followed by quantitative determinations of reducing substances and amino-nitrogen in the separate fractions. More than 6,000 determinations were made on over 900 fractional specimens in the course of the studies. The results showed that:

(1) Mixtures of carbohydrate and protein in the test meal do not, in any way, interfere with gastric secretion.

(2) Not only do these mixtures not interfere with gastric digestion, *but that carbohydrate digestion in the stomach is prolonged and encouraged by its mixture with protein.* This is probably brought about by the more favorable reaction for continued ptyalin activity in the stomach as a result of the acid combining power of the protein. The same would be true following any regurgitation of pancreatic amylase from the duodenum.

I. Effect of Acetylsalicylic Acid Upon Gastric Activity and the Modifying Action of Calcium Gluconate and Sodium Bicarbonate*

By

J. G. SCHNEDORF, M.D.

W. B. BRADLEY, M.D.

and

A. C. IVY, M.D.

CHICAGO, ILLINOIS

LITTLE literature is available regarding the action of salicylates upon gastric secretion, which is rather odd when one considers how widely such medication is employed. Klockman (1) concluded from three experiments upon two dogs which received a test breakfast and 0.5 gm. of sodium salicylate that sodium salicylate decreases gastric secretion and acidity. Leichtentritt (2), on the other hand, reported a rise in gastric secretion in one dog receiving a meal of meat and milk to which was added 0.5 gm. of sodium salicylate. Veil and Graubner (3) observed human cases in which one dose of salicyl compound inhibited the formation of hydrochloric acid. The results of Morris and Graham (4) were inconclusive. Although it is believed that salicylate medication is a cause of gastric anacidity (5), there is no reliable clinical evidence supporting this belief. For example, no one has made control gastric analyses prior to salicylate medication and then has repeated the analyses afterwards in patients.

On the contrary, the use of sodium bicarbonate for reducing local gastric irritation and for preventing the acidosis secondary to salicylate therapy is well known (4, 6). The ameliorating influence of sodium bicarbonate on certain of the undesirable features of acetylsalicylic acid administration has been confirmed recently by Thompson and Dragstedt (7), who also found that calcium gluconate possessed similar, if not greater effects. Certain evidence suggested to these authors that the action of calcium in protecting against salicylism might be due to a systemic influence, such as the protective influence of calcium against carbon tetrachloride poisoning (8). Both sodium bicarbonate and calcium gluconate appreciably decreased local gastro-duodenal irritation and the incidence of ulceration caused by acetylsalicylic acid alone.

Our investigation was undertaken to ascertain the effect of acetylsalicylic acid on gastric secretion and emptying time and to determine if the protective action of sodium bicarbonate and calcium gluconate against the gastro-duodenal irritation associated with acetylsalicylic acid medication may be explained by detectable changes in gastric secretion and motility.

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago.
Submitted March 18, 1936.

METHODS

The effect of single doses of acetylsalicylic acid upon gastric activity was determined on normal human subjects, normal dogs and upon dogs with pouches of the entire stomach. The effect of prolonged daily administration was determined upon normal dogs and upon dogs with Pavlov pouches of the stomach.

Doses of the drug were chosen so that a single administration would not, and did not, provoke nausea and vomiting, but that on continued administration some evidence of gastro-intestinal irritation would be obtained.

Single doses of acetylsalicylic acid: The effect of single doses of acetylsalicylic acid and mixtures of acetylsalicylic acid and calcium gluconate and acetylsalicylic acid and sodium bicarbonate was determined upon ten normal human subjects. The subjects were fasted at least twelve hours before the fractional gastric analysis was conducted upon them. A Rehfuss tube was passed to a distance which allowed the tip to reach the most dependent part of the stomach. The volume of aspirated residual contents was noted and a 1 c.c. sample was titrated with N/10 NaOH for free and total acidity using p. dimethylaminoazobenzene and phenophthalein as indicators. Basal secretions were withdrawn at ten minute intervals for thirty or forty minutes. With the establishment of a basal level of secretion, a control volume of 250 c.c. of distilled water was injected through the tube into the stomach. At ten minute intervals the entire contents of the stomach were aspirated; the volumes were noted and re-injected except for 4 c.c. samples which were kept for analysis. The sum of the volumes recovered at ten minute intervals indicated the degree of gastric retention. Relative acidities of the stomach contents were indicated by a comparison of the titrable acidity at ten minute intervals. Each subject was kept quiet and instructed not to swallow saliva during the test. When the stomach had emptied (contents less than 20 c.c.) the above procedure was repeated with 250 c.c. aqueous solutions of acetylsalicylic acid (1 and 2 gm.) and with acetylsalicylic acid (2 gm.) and calcium gluconate (1 gm.), and acetylsalicylic acid (1 gm.) and sodium bicarbonate (1 gm.).

Five normal dogs were also employed to determine the effect of single doses of aqueous solutions of the drug upon

gastric secretion. After washing the stomachs of the fasted dogs with distilled water, control determinations were made by introducing 250 c.c. of distilled water. In 20 minutes the entire contents were aspirated and replaced by a 250 c.c. aqueous solution containing acetylsalicylic acid (1 gm.) or mixtures of acetylsalicylic acid (1 gm.) and calcium gluconate (0.5 gm.) or of acetylsalicylic acid (1 gm.) and sodium bicarbonate (1 gm.). The volume aspirated at the end of 20 minutes was noted and determinations of titrable acidity and chlorides were made.

Total stomach pouch dogs: (9). The stomach pouch was washed with distilled water and a control perfusion with 100 c.c. of distilled water for one hour was made. The gastric juice was then collected for two 1 hour periods after which the pouch was washed and perfused for one hour with a 100 c.c. aqueous solution of acetylsalicylic acid (0.25 gm.) or of a similar amount of acetylsalicylic acid with calcium gluconate (0.175 gm.) or sodium bicarbonate (0.25 gm.). Following this the gastric secretion was collected again for two 1 hour periods. The 1 hour perfusates were analyzed for titrable acidity and chlorides.

Chronic acetylsalicylate therapy. To determine the effect of prolonged daily administration of acetylsalicylic acid on gastric secretion normal dogs and dogs with a Pavlov pouch of the stomach were used.

Nine normal dogs were fed a test-meal consisting of 200 gm. of food and 250 c.c. of water. Two hours later samples of the gastric contents were withdrawn by means of a stomach pump and titrated for free and total acidity. Three such control determinations on consecutive days gave similar results; the averages of which served as controls. The drug was then administered twice a day for *one month.* Three of the dogs received a total daily dose of acetylsalicylic acid of 3 gm. each; another group of three dogs each received 3 gm. of acetylsalicylic acid and 1.5 gm. of calcium gluconate while each of the last group of three received a similar amount of acetylsalicylic acid with 3 gm. of sodium bicarbonate. Weekly determinations of gastric acidity were made as described above before the drug was administered so that its presence might not alter the acidity due to its acidic properties. The dogs were sacrificed after the experiment and the incidence of gastric ulcers noted.

The Pavlov pouch dogs were standardized to a test meal of 300 gm. of food and 250 c.c. of milk to obtain their normal secretory response. Two 1 hour basal secretions were collected before, and six 1 hour secretions were collected after the meal was given. The secretions were analyzed for free and total acidity. The drugs were then given in perforated gelatine capsules 1 hour before the meal and the effect upon the secretory response was noted. The drug or "mixture" was administered daily over a period of about *three weeks.*

RESULTS

Action of single dose of acetylsalicylic acid on gastric evacuation: Analysis of the protocols (not given) of the effect of single oral doses of salicylates upon human gastric activity yielded the following findings:

One gm. of acelylsalicylic acid had no effect on the 20 or 30 minute evacuation rates in 7 out of 10 subjects, and caused definite gastric retention in 2 and slight retention in 1. Two gms. of acetylsalicylic acid had no effect on the 20 or 30 minute evacuation in 6 of the 10 subjects, and caused definite retention in 3 and slight retention in 1. Acetylsalicylic acid (2 gms.) and calcium gluconate (1 gm.) had no effect on 4, caused slight retention in 2 and definite retention in 4. Acetylsalicylic acid (1 gm.) and sodium bicarbonate (1 gm.) caused retention in 1 and increased the rate of evacuation (stomach emptied faster) in 3 out of 4 subjects. Nausea and vomiting did not occur in any of these subjects.

Acetylsalicylic acid caused definite retention whenever administered in 2 of the 10 subjects. The addition of calcium gluconate added two more subjects to the retention group while the addition of sodium bicarbonate caused an increased rate of evacuation in 3 out of 4 subjects.

It was obviously necessary to ascertain the effect of calcium gluconate alone on the rate of evacuation of water from the stomach. Calcium gluconate (1 gm.) alone was given to 6 subjects. The 20 and 30 minute evacuation rates showed that it caused definite retention in 2, no effect in 2, and slightly increased the rate of evacuation in 2.

Because the day to day variations in the rate of evacuation of water from the stomach varies in some individuals as much as 100 per cent but not more than 20 per cent in others, the precaution of determining the rate of evacuation of water on the day of the experiment prior to the giving of the drug was very important. It should be remarked that, with the exception of three subjects on one occasion each, when acetylsalicylic acid was introduced into the stomach the amount of fluid recovered at 20 and 30 minutes was practically always greater than that recovered in the control water tests. This indicates that the general trend of the effect of acetylsalicylic acid on the evacuation of the stomach is in the direction of retention and when the data is so analyzed this trend is indicated to a greater extent than that exemplified by the analysis of the data given above. The reason for this is that because of daily variations we interpreted a 10 or 15 per cent retention as insignificant. This is the only legitimate way of treating the data.

When the sums of the volumes of fluid removed from the stomach at each ten minute period during the 1½ hour water-test period and the 1½ hour drug-test period are compared, it is found that with but few exceptions a greater volume of fluid was removed from the stomach in the drug experiments (Table I). When expressed in percentage differences the results are as follows: 7 per cent more fluid was removed from the stomach when 1 gm. of acetylsalicylic acid was administered than when water alone was administered, 6 per cent more with 2 gms. of aspirin, and 33 per cent more for a mixture of acetylsalicylic acid (2 gms.) and calcium gluconate (1 gm.), while 33 per cent less was removed with acetylsalicylic acid (1 gm.) and $NaHCO_3$ (1 gm.). These figures, however, express not only the fluid retention but also the gastric secretion. This shows that when the drugs were given the general trend toward retention was accompanied by *either* a greater secretion of acid juice or mucoid dilution fluid, bile stained fluid being obtained in only twelve instances out of eighty tests.

The effect of acetylsalicylic acid upon the rate of gastric evacuation was also studied on five normal dogs. The average effects of 15 determinations at a 20 minute interval after introduction of the fluid into the stomach are shown in Table II. It is shown that at twenty minute intervals acetylsalicylic acid (1 gm.) caused a 27% decrease in the rate of gastric evacuation when compared with the rate of evacuation of water. The values for acetylsalicylic acid (1 gm.) and calcium gluconate (0.5 gm.) show a 38 per cent decrease while acetylsalicylic acid (1 gm.) and sodium

bicarbonate (1 gm.) show an increase of 12 per cent in the rate of evacuation when compared with water.

Action on gastric acidity: Our data on normal human subjects and normal dogs does not warrant any conclusions regarding the action of the drugs employed upon gastric HCl secretion. This is because of the individual variation in the rate of emptying of the stomach because of the inadequacy of the size of the dose that can be employed due to the insoluble nature of the acetylsalicylic acid, because of the acidity imparted by the drug *per se* and, finally, because of the buffer action of the calcium gluconate and sodium bicarbonate administered with the drug.

These results, therefore, indicate only the effect of the drugs upon the acidity of the *stomach contents* irrespective of the cause. In ten normal human subjects a single oral dose of acetylsalicylic acid (1 gm.) caused an average increase in *total titrable acidity* of 27.2 per cent over the water controls. Two gms. caused a 58.5 per cent increase. Acetylsalicylic acid (2 gms.) and calcium gluconate (1 gm.) caused a 48.0 per cent increase. Average results on four subjects, as might be readily predicted, showed that acetylsalicylic acid (1 gm.) and sodium bicarbonate (1 gm.) caused a 72.1 per cent decrease in the total titrable acidity as compared with the water controls.

Averages of fifteen determinations on five normal dogs (Table II) showed that the acetylsalicylic acid (1 gm.) caused an increase of 55 per cent in the total acid and 45 per cent in the total chlorides, the addition of calcium gluconate (0.5 gm.) resulted in an increase of 97 per cent in total acid and 87 per cent in total chloride, while the addition of sodium bicarbonate (1 gm.) to the acetylsalicylic acid (1 gm.) resulted in a 49 per cent decrease in titrable acidity while the total chlorides were increased 41 per cent. The percentage changes are relative to similar stimulation with distilled water. The free chloride determinations were decreased with the addition of calcium gluconate and sodium bicarbonate. This is due to the neutralizing action of these substances upon the acid in the stomach.

*Averages of three dogs on each drug.

chloride secretion by the stomach in response to distilled water and then to an aqueous solution of the drug. The results show that perfusion with an aqueous solution of acetylsalicylic acid (0.25 gm.) for one hour results in a 57.5 per cent increase in the total chloride over a similar perfusion with water. Perfusion of acetylsalicylic acid (0.25 gm.) and calcium gluconate (0.17 gm.) produced an increase of only 28.1 per cent while acetylsalicylic acid (0.25 gm.) and sodium bicarbonate (0.25 gm.) produced a relative increase of only 5.5 per cent in the total chloride as compared with water alone. The gastric secretion collected for two 1 hour periods after the perfusion with water and then the salicylate solutions showed no significant differences. This was probably due to the inadequacy of the dose which was limited by the solubility of the drug. The data show that none of the solutions stimulated gastric secretion by local contact with the stomach. The increase in total chlorides being due to the secretion of a mucoid diluting fluid, which shows that acetylsalicylic causes more mucoid secretion to be formed than the acetylsalicylic acid and calcium gluconate mixture and that the acetylsalicylic acid and sodium bicarbonate caused the least formation of mucoid diluting secretion. It was impractical to assay for mucin, since the calcium gluconate precipitated it out of solution in the stomach.

Thus, these results on a pouch of the entire stomach show that acetylsalicylic acid by local contact with the stomach does not increase the output of hydrochloric acid. It does cause an increase in the secretion of a diluting fluid which generally occurs when the stomach is irritated. On this basis, the results show that sodium bicarbonate and calcium gluconate decrease the local irritative action of acetylsalicylic acid on the stomach.

Chronic daily salicylate medication: The average effects of daily oral administration of salicylates to the normal dog (3 dogs) over a period of one month are shown in Table IV. Acetylsalicylic acid (3 gms. per day) showed an average increase of 17.4 per cent in the total titrable acid above the control two hours after the meal. On a similar amount of acetylsalicylic acid given with calcium gluconate (1.5 gms.) there was only a slight average increase of total acidity (2.7 per cent) while with sodium bicarbonate (3 gms.) and acetylsalicylic acid (3 gms.) the average total acidity was actually depressed (27.1 per cent) below the control average. On autopsy two out of three dogs receiving acetylsalicylic acid alone had an ulcer, two out of three receiving acetylsalicylic acid with sodium bicarbonate had an ulcer, and one out of three receiving acetylsalicylic acid with calcium gluconate had an ulcer.

These results show that the continued daily administration of acetylsalicylic acid over a period of a month in the doses used causes an increase in the gastric secretory response to a test-meal. The addition of calcium gluconate prevented this increase; whereas, the addition of sodium bicarbonate resulted in a decreased secretory response to the test-meal.

In the Pavlov pouch dogs (Table V) daily oral administration of acetalsalicylic acid (0.2 to 0.25 gms. per kilo) for about three weeks caused an average increase in the volume of the gastric juice collected of 58.1 per cent with an average increase of the total acid output of 55.8 per cent above the control values. The augmentation was not evident until 3 or 4 days after medication was instituted, a maximum being reached at about 10 days. The secretion returned to normal about a week after withdrawing the drug. Administration of calcium gluconate (0.1 to 0.125 gms. per kilo) with the acetylsalicylic acid over a similar period of time caused an average increase of 23.3 per cent in the volume and an increase of 24.2 per cent in the acidity of the gastric secretion. When sodium bicarbonate (0.2 to 0.25 gms. per kilo) was given with the acetylsalicylic acid, the volume was decreased to 17.1 per cent, the total acid was decreased to 17.2 per cent below the control values.

Thus, the results on Pavlov pouch dogs are analogous to those obtained on the foregoing group.

It should be noted that in the dogs receiving daily acetylsalicylic acid medication, vomiting was evidenced on about the third day and continued intermittently for about ten days. When vomiting occurred, of course, the results for that day had to be discarded, though as a rule the meal was ingested later. Under such conditions it is well known that gastric secretion is depressed and such secretory results are not reliable. When calcium gluconate was given, vomiting was not frequent in its occurrence and did not appear until later, the sixth day, and the dogs also ate their food more quickly. Sodium bicarbonate also ameliorated the symptoms of partial anorexia and vomiting, but not so definitely as calcium gluconate. Our observations on the effect of calcium gluconate and sodium bicarbonate on the time of occurrence of vomiting are at variance with those of Thompson and Dragstedt (7), who observed no significant influence of the two "protectives" on the time of onset and frequency of vomiting. But they administered larger doses of acetylsalicylic acid, and our dogs were obviously, because of the nature of the experiments, under close daily observation, in the case of the Pavlov pouch dogs under observation for eight hours daily.

DISCUSSION

The results show that acetylsalicylic acid in single doses (1-2 gms.) in water causes a definite gastric retention in some human subjects and an increase in the titrable acidity of the gastric contents in all. This re-

tention and increase in titrable acidity was also observed in five normal dogs. When the drug was given over an extended period to dogs, a definite increase in the total output of HCl occurred in Pavlov pouch, as well as normal dogs, when a test-meal was fed.

Since in Pavlov pouch dogs the drug does not come into direct contact with the mucosa of the pouch, the augmented secretion of acid observed can only be due to reflex excitation or to circulating substances. That the augmented secretion is not due to local contact of the drug with the gastric mucosa is further shown by the failure of the pouch of the entire stomach to be stimulated by perfusion with the drug, although a portion of the drug was absorbed by the gastric mucosa. To determine whether the drug acts predominately through the reflex or the humoral mechanisms would constitute a prolonged and difficult study. Whichever mechanism is involved, it is influenced in an accumulative manner, since a definite increase in production of hydrochloric acid is not evident until several days after medication is started.

In regard to the ameliorating action of sodium bicarbonate and calcium gluconate on the gastric disturbances caused by acetylsalicylic acid, the results show that sodium bicarbonate decreases the gastric retention and the total titrable acidity of the gastric contents when given with single doses of acetylsalicylic acid more effectively than calcium gluconate. Also, sodium bicarbonate when given daily with acetylsalicylic acid over a prolonged period prevents the increased gastric secretory response to a test-meal more effectively than calcium gluconate. The same is true when one uses the amount of diluting secretion formed by the gastric mucosa as a criterion of irritation, *i.e.*, sodium bicarbonate reduces the irritation of the gastric mucosa by acetylsalicylic acid more than calcium gluconate. Further, less absorption of acetylsalicylic acid by the gastric mucosa occurs when sodium bicarbonate is used with the drug than when calcium gluconate is used. These observations indicate that sodium bicarbonate should be more effective in ameliorating the local irritative effects of acetylsalicylic acid on the gastro-duodenal mucosa than calcium gluconate. In fact, one may account for the ameliorating action of sodium bicarbonate entirely on the basis of the effects observed in this study; this is not the case for calcium gluconate. Yet, it would appear from our observations, which, as far as they go, confirm those of Thompson and Dragstedt, that calcium gluconate is as effective as sodium bicarbonate, if not more so, in ameliorating gastro-duodenal irritation, and that the ulcers, which result from acetylsalicylic acid medication, are in part due to some systemic disturbance which calcium tends to ameliorate. Either calcium protects by some systemic action, or calcium gluconate reduces the "acid irritation" below a certain minimum necessary for the production of ulcer, or both.

Thus, it follows from our observations and those of Dragstedt and his collaborators that when acetylsalicylic acid, or a salicylate, is given in large doses the optimum protection would be attained by giving both sodium bicarbonate and calcium gluconate. We cannot speak in this regard for other salts of calcium, since we did not use them.

*Averages of daily determinations for about three weeks. Figures indicate total volume and acidity of gastric secretion for six hours following meal.

CONCLUSIONS

1. In some normal human subjects and normal dogs, single oral doses (1-2 gms.) of acetylsalicylic acid caused gastric retention; the addition of calcium gluconate tended to increase the degree of retention while the addition of sodium bicarbonate increased the rate of gastric evacuation.

2. In normal human subjects and normal dogs, single oral doses of acetylsalicylic acid increased the total titrable acidity of the stomach contents; the addition of calcium gluconate diminished the rise in the acidity, while the addition of sodium bicarbonate decreased the acidity of the contents below that of the controls.

3. In dogs with pouches of the entire stomach, the local application of acetylsalicylic acid caused a definite increase in the neutral chloride, or diluting secretion of the stomach, the addition of calcium gluconate resulted in only a slight increase in the diluting secretion, while the addition of sodium bicarbonate to the acetylsalicylic acid also resulted in only a slight in-

crease in the diluting secretion. None of the solutions increased the formation of HCl significantly.

4. Prolonged daily administration of acetylsalicylic acid to normal dogs to dogs with Pavlov stomach pouches resulted in definite augmentation of gastric secretion. With the addition of calcium gluconate the increase was not nearly so marked, while sodium bicarbonate and acetylsalicylic acid actually caused a decrease in the gastric secretion below the control values.

5. The neutralizing and "inhibiting" actions of sodium bicarbonate and calcium gluconate on the titrable acidity of the gastric contents, and on the output of hydrochloric acid under the conditions of our experiment may play a definite role in the ameliorating effects of these substances upon the degree of gastric irritation and the incidence of ulceration produced by the prolonged oral administration of acetylsalicylic acid to dogs. Whereas the protective action of sodium bicarbonate may be adequately explained by a reduction of acid irritation, this is not true of calcium gluconate, whose protective action against digestive disturbances appears to be due also in part to some systemic action of calcium.

6. From the evidence available it would appear that to obtain optimal protection when giving salicylates in large doses, the salicylates should be administered with sodium bicarbonate and calcium gluconate.

SECTION VI—*Abdominal Surgery*

Problems in Obstructive Jaundice Cases

By

D. PHILIP MacGUIRE, A.B., M.D., F.A.C.S.*

NEW YORK, NEW YORK

RESPONSIBILITY for the preparation of obstructive jaundice patients for operation should be jointly shared by (a) the department of blood chemistry, (b) the internist and his staff, and (c) the anesthetist and the operating surgeon.

Hemorrhage should be given first consideration since over 50 per cent of the fatal cases are due to this factor.

Smith (1) was the first to demonstrate the seriousness of this complication, although, there had been previous reference to it.

Some of the early investigators who believed that the circulation in the blood of an excess bile pigment was responsible for the hemorrhagic tendency were Morawitz and Bierich (2), King and Stewart (3), King, Bigelow and Pearce (4). Morawitz and Bierich (2) believed that bile acids caused this condition.

The work of Brakefield and Schmidt (5), and of Snell, Greene and Rowntree (6) has made it evident that neither the bile pigments nor the bile acids, *per se*, are responsible for the hemorrhages encountered in these cases.

Wright (7) was the first to suggest the use of calcium in hemorrhagic patients. Mayo Robson (8) proposed its use to terminate the bleeding in obstructive jaundice. Schmerz and Wischo (9) discovered that the intravenous injection of calcium lactate into normal human beings shortened the coagulation time of the blood. Kirk, King and Emerson are included among those who made further investigations which revealed that the calcium content was only moderately reduced in the blood serum of icteric patients.

Kerr, Hurwitz and Whipple (10) produced necrosis of the liver in dogs by the subcutaneous injection of phosphorus. They discovered that the blood of the animals would not clot.

It is well known that the main source of fibrinoglobin is the liver. This fact was mentioned by Foster and Whipple (11). The liver is also intimately associated with the production of hemoglobin, according to Whipple.

This brings up the question as to whether there is a substance present, in the damaged liver, which inhibits or delays the clotting.

Since it has been concluded that the hemorrhagic tendency in obstructive jaundice is not caused by the accumulation of bile pigments or bile acids in the blood, and Snell and Greene (12), of our hospital staff (formerly associated with the Mayo Foundation), have demonstrated the following facts to be true: (a) that there is no correlation between either the total or the diffusible content of the calcium of the serum, and (b)

*Assistant Clinical Professor of Surgery of the N. Y. Post-Graduate Medical School and Hospital, Columbia University.

Submitted March 11, 1936.

neither the serum bilirubin nor the delay in the coagulation of the blood in the presence of jaundice, one may infer that some disturbance of the blood calcium may exist in obstructive jaundice, but that its relationship to hemorrhage is rather indirect and is still unknown.

The relationship of fibrinogen to bleeding must also be considered. It has already been noted that the liver is the potent source of fibrinogen; this was confirmed by Whipple and Foster (11). Some observers are convinced that bleeding may be due to a lack of fibrinogen in obstructive jaundice. Moss (13) concluded that the hemorrhagic tendency in these cases was not associated with a deficiency of fibrinogen in the plasma, but that there really was an increase in fibrinogen in a ratio to the changes in the liver condition.

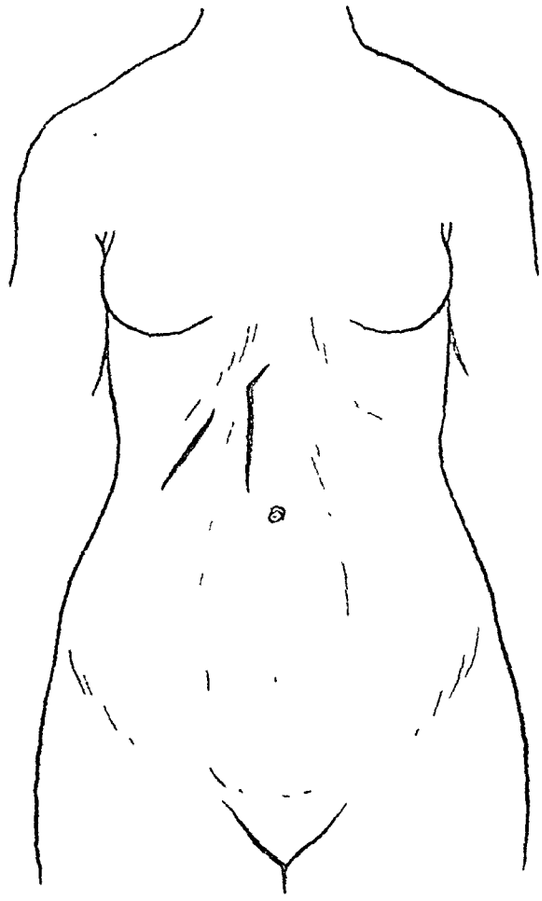

Fig. 1. Primary Incision.

Clinical obstructive jaundice patients have a visible discoloration of the skin, mucous membranes and sclera. Chemically, they have a retention and accumulation of bilirubin in the blood serum. The normal content, circulating in the blood, varies from one part of bilirubin to from 400,000 to 600,000 parts of blood serum. When the concentration reaches from 1 to 40,000, the skin becomes tinged and clinical jaundice appears. Icteric index is the measure of intensity of color of the blood serum as compared with a standard. The normal icteric index varies from 3 to 6. The clinical evidences of jaundice are usually obtained when it reaches 20 or more. Between 6 and 20 is the latent period. Kupffer's cells in the liver and the reticular cells of the spleen are concerned in the breaking down of the hemoglobin into bilirubin. Jaundice arises from the obstruction of the outlet of the bile capillaries after the changed bilirubin has passed through the polygonal cells of the liver plus the bile salts and consequent obstruction and absorption. Obstructive hepatic jaundice presupposes a normal bile formation and a normal mechanical excretion through the apparently normal liver cells. This mechanism does not continue for any great length of time after obstruction has occurred, for normal bile is no longer secreted nor are the liver cells intact. In the beginning, the jaundice becomes obstructive due to a mechanical factor. This does not remain long, for as soon as the obstruction raises the hydrostatic pressure of the fluid within the ducts to a degree equal to that of the secretory liver pressure, there must, of necessity, be a cessation of flow or even a reversal of direction of the bile current with a function conductive to intrinsic damage to the liver cells. Bile salts are the specific products of the liver parenchyma. The production of bilirubin, together with bile salts, is a function limited to the liver. No other organ can simultaneously produce these two chemical substances. Along with bilirubin, bile acids are always present in normal blood. With the Szilard method, the bile acids of normal blood vary from 5 to 12 mg. with an average of 7 mg. Katayama, by a modification of this method, failed to find bile acid in normal urine. An abnormally rapid rate of hemolysis elevates the bilirubin of the blood serum, but does not influence the concentration of bile acids. On the other hand, the production of liver damage increases the bile acids; but this has relatively little effect upon the bilirubin of the blood serum. Even in cases of cholecystitis with transient biliary obstruction, there is a very definite increase in bile acids of the blood serum. The concentration of bile acids is also greater in some cases with normal icterus indices than in others with hyperbilirubinemia. Therefore, it is of paramount importance to determine the bile acids in the blood, in addition to bilirubin, since the increase of bile acids is an absolute indicator of liver injury. Urobilinuria is also an index as to the extent of the impairment of liver function. Normally, it does not exceed 30 mg. in 24 hours by the method of Elman and McMaster. However, in obstructive jaundice, urobilin is negative and excreted in minute amounts forming a striking contrast to catarrhal jaundice. On the other hand, in obstructive jaundice, there is an increased elevation of the icterus index disclosing a hyperbilirubinemia. The bile acids are increased above normal but they do not parallel the icterus index. There is also a distinctive change in the chemical composition of the blood in obstructive jaundice as shown by an increase of cholesterol which is present in two forms: (a) free alcohol, and (b) combined with acid as esters. Normal blood contains from 160 to 200 mg. per 100 ml. In obstructive jaundice, it is increased and may even reach 1,000 per 100 ml. The icterus index, in these cases, may go as high as 200, bile acids to 75 mg. per 100 ml., and direct and indirect van den Bergh, four plus.

In making an estimate as to the extent of the impairment of liver function, the determination of nonprotein nitrogen, urea, uric acid, and the amino acid nitrogen, which must be made daily, (preferably in the morning), are essential to an adequate estimation of complete liver function, and for the differentiation of the types of jaundice. Biochemical analyses must include icterus index, bile acids, blood sedimentation test, cholesterol, nonprotein nitrogen, urea and amino

nitrogen, uric acid of the blood, and urobilin excretion in the urine.

Blood sugar determinations are necessary since the carbohydrate metabolism is also disturbed by virtue of the fact that the liver regulates, quantitatively, the amount of carbohydrate that is furnished to the body cells in the varying conditions of carbohydrate intake

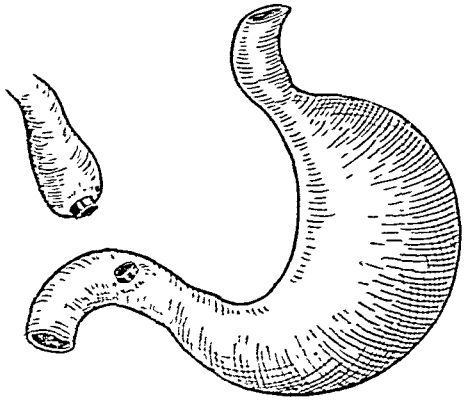

Fig. 2. Insertion of Murphy Button, Anastomosing Gall Bladder and Drainage Tube.

and bodily activity. The internist should order insulin in the suitable cases.

There is a kidney dysfunction in many of these patients. Three distinct procedures should be used to determine renal efficiency. Each of them is based on different principles. The method described by Lashmet and Newburgh (14) is advocated for measuring the concentrating ability of the kidneys. The urea excreting-function should be gauged by the urea clearing test of Van Slyke since it has been generally accepted due to its practical demonstrated worth. The efficiency of dye elimination should be measured by the fifteen-minute phenolsulphonephthalein excretion test because Van Slyke (15) and others have shown that the two-hour phenolsulphonephthalein excretion test measures impairment of kidney function only when extensive renal damage actually exists. According to Chapman and Halsted (16), the excretion of this dye, during the first fifteen minutes following its injection, is decidedly a more sensitive test which is really comparable with the urea clearance as a measure of renal efficiency.

Mosenthal and Bruger (17) recently reported that the "urea ratio" (the percentage of the nonprotein nitrogen which is urea nitrogen, *i. e.*, $\frac{\text{nonprotein nitrogen}}{100 \times \text{urea nitrogen}}$) is a satisfactory index of renal efficiency. They believe that the urea ratio is a correct indication of kidney function despite the fact that the concentration of both urea and nonprotein nitrogen are within normal limits in the blood. Their method is most acceptable since there is an excellent agreement between the urea ratio and the urea clearance.

Since over fifty per cent of the fatal issues are due to postoperative hemorrhage, the clotting time of the blood is a very essential test. In many of these icteric patients, there is a hypochlorhydria, as is evidenced by the blood determination of the chlorides. Inflammatory infiltration about the ducts and even about the finer channels within the hepatic lobule, along with exfoliated epithelium and thrombic formation within the ducts, themselves, are further evidences of the severe injury to the liver.

The various tests enumerated above, together with the routine physical examination, including Wassermann test, blood count, especially Schilling, cardiogram and roentgenogram, impress one with the seriousness of the problem in these patients and also the importance of group consultations, particularly, as to the advisability of operative procedure. In the long-standing, toxic jaundice patients, surgeons are entitled to a helpful sympathy since the operative mortality rate is high.

One of the most important functions of the liver is the protection of the body against poisonous substances which are formed in the intestines. The fact has been established also that much of the power of the liver to carry out this detoxicating function depends upon its glycogen content. As early as 1892, Roger (18) recognized the detoxicating action of the liver. The experiments of Graham (19) and of Opie and Alford (20) should convince one of the extreme importance of the introduction of glucose or dextrose solutions.

For some time, investigators have been convinced that the liver produced an anticoagulant in patients with jaundice. The majority of them have professed ignorance concerning the exact cause of hemorrhagic tendencies in this disease.

When proper consideration for the preparation of these icteric subjects is made, the amount of dextrose or glucose solutions to be administered should not be estimated in centimeters but in quantities of liters or gallons. For many years, it has been generally known that the intravenous injection of 5% solution of dextrose or glucose does not produce any harmful effects upon the vein. General preference is usually given to the Hendon, Tauroff or Lindeman needles to be used for the injection. Large amounts of the 10% solution may be administered by utilizing the Murphy drip. The 5% solution is generally injected under the skin. Ampules of a 25 to 50% solution of glucose in 50 to 100 c.c. quantities should ke kept in reserve for emergencies. A high caloric diet, supplemented with highly sweetened fruit juices, is recommended for the patient's nourishment. Having properly classified the type of the patient's blood, two or three donors should be held available, pending the possible need for massive blood transfusions. It is well to bear in mind that 65% of the body weight is composed of water. Consequently, a patient weighing 100 Kg. has a total water estimation of 65 Kg. or 6500 centimeters. A 10% loss in water may prove fatal to the patient.

Judd, Snell and Hoerner (21) were the first to present an apparently reasonable explanation regarding the increase in coagulability of the blood in jaundiced patients by the use of blood transfusion. They have shown that anoxemia was present in some instances of jaundice. In the presence of a serious liver condition, anoxemia predisposes a hemorrhagic tendency. These three investigators state that there are two types of this affection: *viz.*, anoxic anoxia and anemic anoxia. The first can be corrected by placing the patient in an oxygen tent, and the second by blood transfusion. They suggest that the hemoglobin is changed in these

cases and that oxygen is not omitted in a like amount as in normal or transfused blood.

At the present time, some investigators may become intrigued with the idea of carrying on experiments to obtain a liver extract, produced from the parenchyma of the organ, in order to determine whether this fluid will help to counteract the anticoagulating substance

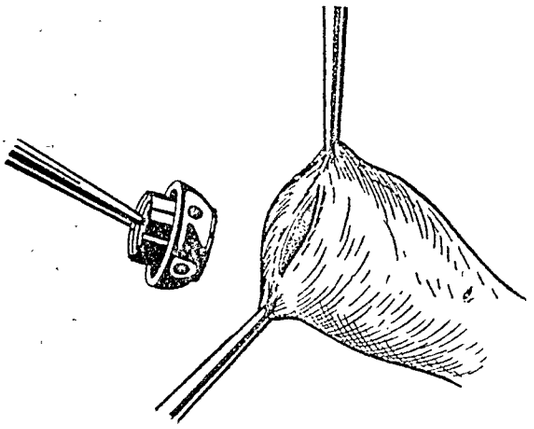

Fig. 3. Secondary Incision.

developed in the injured, diseased, or toxic livers existing in cases of obstructive jaundice.

In presenting this article, it has been the aim of the author to appeal to laboratory workers, sufficiently interested in this condition, to attempt to produce some extract or serum that will help combat this anticoagulating process of the diseased liver.

OPERATIVE CONSIDERATIONS

Without exception, all operative procedures should be performed in two stages. The first is to institute drainage of the gall bladder when the obstruction is below the entrance of the cystic duct which is true in about 90 per cent of instances. This is accomplished by using a modification of the Kocher or Courvoisier incisions, making it more longitudinal, as in Fig. 1. After a thorough exploration of the common duct and having determined the point of obstruction, the gall bladder fundus is then brought up to the aperture of the abdominal incision. Following sufficient packing and walling off, this viscus is drained with a trocar and cannula connected with a rubber tube; the edges of the aperture are held taut with Allis clamps. The female portion of a small size Murphy button is next introduced into the opening of the gall bladder. The male end of the button is inserted into one end of a long rubber drainage tube. The corresponding parts of the Murphy button are then snapped together. In this way, intermittent drainage is instituted and only small quantities are permitted to drain away since one of the most serious factors, at this operative stage, is the danger of a sudden release of suppressed bile which would result in a decrease of the pressure in the common duct. This, in turn, would accelerate the reduced flow of portal blood in the liver and would wash out the toxic substances from the damaged organ into the general circulation. There are several advantages in using the Murphy button, *viz.*, the absolute hemostasis of the edges around the opening of the gall bladder, its quick disconnection, and a further important function to be performed in the secondary stage of the operation. Some surgeons prefer a 28 or 30 F. Pezzer catheter. Following the drainage, performed under local anesthesia, a chemical analyses of the material obtained and a further check-up in the blood and urine chemistry is regularly made. The improvement evidenced by some of these cases after a 72 hour drainage may be amazing.

The consultants having agreed upon the time for the second stage of operation, the operating surgeon proceeds to make a Mayo-Robson or Mayo incision. Spinal anesthesia may be administered, providing the condition of the patient warrants it. However, the Author advises the use of a more modified anesthetic, such as cyclopropane, ethylene combined with a local anesthesia, or avertin, in small amounts may be used as a preliminary anesthetic. The Mayo-Robson incision is closer to the median line than the first one. If the operator discovers that he is dealing with a malignancy of the pancreas, he should disconnect the gall bladder fundus, containing the Murphy button, and use the other end of the button that was inserted in the drainage tube. After proper sterilization, the neighboring first portion of the duodenum or stomach should be incised and this part of the Murphy sutured in and the two parts connected. Drains should then be inserted down to Morrison's pouch and also to the Murphy button anastomosis.

If the obstruction consists of a large impacted stone situated in the lower portion of the common duct, as is so often the case, this area should be dealt with by reflecting and retracting the second portion of the duodenum having, first, incised the peritoneum on the right side. This approach is quite simple and easy as compared with McBurney's transduodenal technic. A T-shaped tube is then inserted. The gall bladder is not to be disturbed since there is an actual or potential pancreatitis to counteract and the gall bladder drainage is most essential in this complication.

After exploring the cause of the obstruction, if a complete stenosis of the lower part of the common duct is found with repair of this organ out of the question, the proximal stump must be used and the end is then

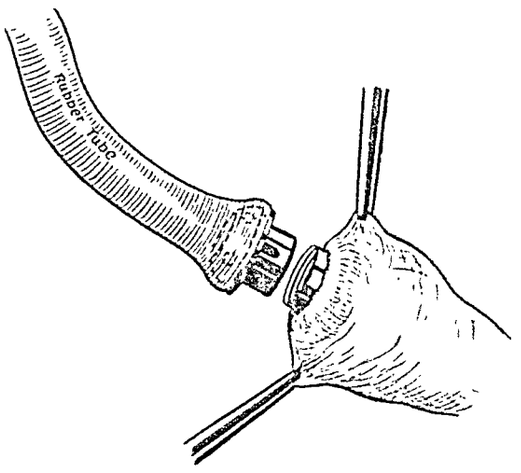

Fig. 4. Anastomosing Gall Bladder and Pylorus with the Murphy Button.

inserted into the proximal duodenum. If the end, to be inserted, is split into four parts, using longitudinal incisions of half a centimeter, each of these parts can be sutured to the duodenal wall, following their insertion, by first threading a nontraumatic suture through the edge before its introduction into the proximal duodenum. Greater security is given, along with

the bile current, by keeping the edges open so that no stenosis can occur.

A direct anastomosis should be used in cases of common duct stenosis even when there exists a virtual destruction. It is made possible by hooking a dull retractor, shaped like an aneurysm needle, over the V-shaped juncture of the hepatic ducts to steady the anastomosis. This is especially true in thin subjects where it is comparatively easy to repair the tissues even though a small portion of the common duct is left with which to make an anastomosis between the duodenum and the common duct.

Unless otherwise unavoidable, the Author wishes to emphasize that the old, obsolete technic, exemplified by the Sullivan tube method, in which a space is left filled in by a rubber tube and covered over by various methods, should not be used. From personal observation, the writer has found that very few operations of this kind have been successful since the stenosis becomes more acute and the adhesions aggravate the extreme seriousness of further exploratory dissection. Therefore, a direct anastomosis of at least a part of the cut edges of the common duct is essential. Failing to accomplish this, an anastomosis of even a small stump of the upper portion of the common duct to the duodenum should be made. On the cadaver in thin subjects, it offers no great difficulty.

CONCLUSIONS

To improve coagulation, transfusions of whole blood and glucose solutions should be administered. At the present time, the extreme value of these solutions in this complication is more fully appreciated, a fact which was unknown a few years ago. The Author has entirely discontinued the calcium solutions which he formerly used to decrease the clotting time, since massive blood transfusions have wholly supplanted the older methods. Ten per cent calcium chloride solutions and ampules of calcium gluconate are useful in order to increase the blood calcium only to the extent of calcium deficiency. Chloride deficiency is improved by the introduction of normal saline and diluted hydrochloric acid solutions by mouth. One dram should be given daily in divided doses, gradually increasing the amount, hypertonic solutions should be introduced intravenously if a serious chloride deficiency exists. The administration of insulin should be made in patients who show increased blood sugar. The diet consists of various fruit juices and cereals, unless contradicted by some special complication.

These patients suffer a fall in body temperature during the course of the operative procedures. This condition must be counteracted by the use of hot laparotomy pads, short exposures, and a warm operating room.

The loss of fluids, brought about by the drainage, must be counter-balanced by the introduction of a glucose or dextrose solution. The drainage may be clamped for a certain length of time during the course of each hour. The Author wishes to reiterate the extreme caution that should be exercised, when drainage is instituted, to regulate the escape of bile to small amounts.

The time-factor is one of the most serious considerations because, at best, these icteric patients are poor surgical risks. It is necessary to make a thorough check-up in order to ascertain that the drainage tubes, Murphy buttons and syringes are in perfect condition prior to operation. This may appear strange to the uninitiated, but the Murphy buttons fit only in pairs and drainage tubes have been known to have had a lumen that was imperfect.

There appears to be little or no excuse for the delay in sending these patients to a hospital for proper diagnosis and preoperative treatment. Yet, daily, subjects are admitted in the late stage of jaundice due to obstruction.

Experimental Peptic Ulcer*

The Effect of Surgical Duodenal Drainage Upon Dogs and the Value of Histidine in Preventing Ulcer

By

CHARLES A. FLOOD, M.D.

and

CLINTON R. MULLINS, M.D.

NEW YORK, NEW YORK

A. G. Weiss and E. Aron, in 1933 (1), reported that daily injections of histidine prevented the formation of peptic ulcers in dogs that had been subjected to the operation of surgical duodenal drainage. Their report contains one series of four animals and another series of two animals treated with histidine and sacrificed three to ten weeks after operation. Of these six dogs only one developed an ulcer and the latter was ascribed to a technical oversight. Inasmuch as many workers (2, 3, 4, 5) have shown that this operation usually yields peptic ulcers in almost 100 per cent of dogs, these findings seemed significant. Weiss and Aron explained their results on the assumption that the ulcers which develop in dogs with physiological exclusion of the duodenum are due to a "general disturbance of metabolism based upon a lack of the indispensable amino-acid, histidine." They also emphasized the loss of weight and anemia which develop in these animals as being manifestations of deficiency. This report led shortly to the widespread use of histidine in the treatment of patients with peptic ulcer. Meanwhile there have been, to our knowledge, no reported attempts to confirm the original experimental findings.

Our own experiments were undertaken for this purpose. It was considered advisable to have a larger series of animals and to allow them to survive for longer periods of time than did Weiss and Aron. During the course of the investigation numerous physiological and pathological changes resulting from surgical duodenal drainage apart from the development of ulcer were found. These findings are reported here in detail because they have not received due emphasis in the literature, even though the administration of histidine had no apparent effect upon them.

EXPERIMENTAL METHODS

Nineteen dogs ranging in weight from 9 to 18 kilograms were subjected to surgical duodenal drainage according to the technique of Mann and Williamson (2) with minor modifications. The duodenum was divided at a point about 1 centimeter beyond the pylorus and the jejunum was divided about 10 centimeters below the ligament of Treitz. The lower end of the resulting isolated loop of bowel was anastomosed (side to side) with the terminal ileum at a distance of 25 to 40 centimeters from the ileocecal valve, after closing both open ends of the loop with purse string sutures. The continuity of the intestinal tract was reestablished by an end to end anastomosis of the jejunum with the short remaining portion of the duodenum adjacent to the pylorus. Fine plain catgut was used for the intestinal anastomoses. No clamps were applied to the gut during the operation.

After operation the dogs received daily saline and glucose infusions and no food or water was given by mouth for four days. The animals were then placed on the regular diet of the Animal Care Department which includes meat scraps and bones, vegetables, rice, bread and milk. The dogs were permitted to survive until moribund or until death occurred unexpectedly. Routine autopsies were done on all animals including microscopic study of the thoracic and abdominal organs of most of them.

Blood chemistry studies were done on some animals before operation and at intervals after operation. All blood samples were obtained 24 hours after feeding and at least four hours after food pans had been withdrawn. Total blood amino nitrogen was determined by the Folin colorimetric technique using a glycine standard. The methods for the other blood determinations were those used by Atchley, Loeb and Benedict (6, 7) in work previously reported from this department.

Tissue analysis for amino nitrogen content was made by means of an adaptation of the method of Folin for blood amino nitrogen. Small portions of the stomach and proximal jejunum were removed within one to two minutes after the animal was sacrificed and dropped into approximately 10 centimeters of distilled water at a temperature of 90° C. to stop autolysis. The tissues were then weighed while moist and ground finely with sand. The volume of the mixture after grinding was brought up to 60 c.c. by the addition of water, 6 centimeters of 10 per cent sodium tungstate and 6 centimeters of two-thirds normal sulphuric acid. After shaking, the mixture was filtered. The determination of amino nitrogen was then made according to the Folin technique using 3 to 5 centimeters of the filtrate for the unknown and comparing against a standard containing 0.07 mg. of glycine. The final mathematical calculation was made as follows:

$$\frac{60 \times .07}{\text{c.c. of filtrate} \times \text{weight of tissue} \times 2} \times \frac{U}{S}$$

In some animals, gastric secretion was studied before and after operation. For this purpose a broth meal was used which was given by stomach tube. This procedure was adopted for fear that some animals might refuse to eat a test meal voluntarily when cachexia developed, and also because the normal acid response to broth is slight and any increment in acidity after operation could be easily detected. The meal consisted of 200 c.c. of 1 per cent Liebig's beef extract. Gastric contents were withdrawn either 30 minutes or one hour after the meal was given and the concentrations of free and total acid were determined by titration with N/100 sodium hydroxide using Toepfer's solution and phenophthalein as indicators.

RESULTS

Effect of Histidine upon the Development of Jejunal Ulcers: Surgical duodenal drainage was performed upon 19 dogs, 17 of which survived the immediate

*From the Departments of Medicine and Surgery, College of Physicians and Surgeons, Columbia University and the Presbyterian Hospital, New York City.

Submitted February 28, 1936.

post-operative period. In order to determine whether injections of histidine would protect against the formation of ulcers the animals were divided into two groups. Group I, consisting of five dogs, was a control group to which no histidine was given and in which jejunal ulcers could be expected to develop. Group II, composed of 12 dogs, received l-histidine monohydrochloride made up in a 4 per cent solution in distilled water and administered intramuscularly once a day immediately before the animals were fed.

of the first portion of the jejunum not involving the muscular coat. The latter animal had died accidently of acute intestinal obstruction. Eliminating this animal which might have developed a true ulcer of the jejunum if it had survived for a longer period, five out of eleven, or 45 per cent of the dogs which received histidine failed to develop ulcers in contrast with the control group in which all had ulcers. There was no correlation between the size of the dose of histidine and the formation or absence of jejunal ulcer.

TABLE I

Results of histidine administration to dogs with surgical duodenal drainage. Dogs No. 1 to 5 received no histidine. Dogs No. 6 to 17 received daily injections of histidine

Dog No.	Pre-op. weight kg.	Per cent of body weight lost after operation	Post-op. duration of life	Mgs. of histidine—HCl per kg. of initial weight	Result
1	13.9	48	63 days	None	Three jejunal ulcers with one perforation. Peritonitis.
2	17.1	49	51 days	None	Three jejunal ulcers with one perforation. Peritonitis.
3	10.0	47	63 days	None	Perforated jejunal ulcer. Several erosions in antrum. Peritonitis.
4	9.0	40	63 days	None	Three jejunal ulcers. One walled off perforation.
5	10.9	44	104 days	None	One shallow jejunal ulcer.
6	11.0	39	59 days	7.3	No ulcer or erosions.
7	13.8	47	75 days	5.8	No ulcer or erosions.
8	11.0	52	55 days	7.3	No ulcer or erosions.
9	16.8	44	94 days	4.8	Single indurated ulcer just distal to gastrojejunal anastomosis.
10	9.0	33	87 days	8.8	Small perforated jejunal ulcer.
11	13.2	37	41 days	7.6	Large single jejunal ulcer.
12	9.0	31	31 days	8.8	Single jejunal ulcer.
13	11.9	42	40 days	6.8	No ulcer or erosions.
14	17.5	42	56 days	6.9	Small superficial erosion in jejunum.
15	11.8	43	49 days	6.7	Multiple ulcers in jejunum.
16	11.0	47	82 days	10.9	No ulcer or erosions.
17	13.5	34	57 days	8.9	Large perforated ulcer in jejunum.

The dosage was varied for different animals as shown in Table I, ranging between 4.8 and 10.9 mg. per kilogram of the body weight before operation.

Group I: The five control animals survived 51 to 104 days after operation. Three of them died of general peritonitis due to perforated jejunal ulcers. The other two were sacrificed when moribund and found to have jejunal ulcers which in one dog had perforated and been walled off by adhesions. The ulcers were multiple in three of the animals and solitary in the other two and all were located in the first portion of the jejunum a few mm. beyond the line of anastomosis with the stomach.

Group II: The 12 dogs which received daily injections of histidine survived for 31 to 94 days. Three died of cachexia, one of hemorrhage from a jejunal ulcer; one died of acute intestinal obstruction due to a peritoneal band on the 56th day and seven were chloroformed when moribund. Six of the 12 dogs showed jejunal ulcers which in two instances had perforated and been walled off by adhesions. In one of these six the ulcers were multiple and the other five had solitary ulcers of the jejunum. Of the remaining six animals in the group, five were found to have no ulcers or erosions and one had only a small superficial erosion

CLINICAL PICTURE IN SURGICAL DUODENAL DRAINAGE

The course after operation was characterized by a gradual almost continuous loss of weight and strength and was the same in both groups of animals. The duration of life ranged between 31 and 104 days, averaging about two months. Loss of weight occurred in spite of a fairly normal appetite, the dogs usually eating well throughout the post-operative course, except for the last several days of life when they usually were too weak to stand up and eat. The total loss of body weight in the entire group at death varied between 31 and 52 per cent of the initial weight.

Watery diarrhea was noted frequently during the first two weeks after operation but was uncommon during the remainder of the course. Tarry stools also did not occur after the first few post-operative days until late in the picture. Stool guaiac determinations were done at intervals in an effort to detect the presence of ulcer but were frequently negative in animals which were demonstrated to have ulcers shortly afterward. Stools were also stained for neutral fat and fatty acid crystals but no increase in the amount of unabsorbed fat was found except on one occasion.

As time progressed the buccal mucosa became very pale. In a few instances ulcerative stomatitis developed terminally. A striking feature which was usually noted within a few weeks after operation was weakness of the extremities, more particularly of the hind quarters. Death finally occurred, usually as a result of cachexia or perforated ulcer.

CHANGES IN BLOOD CHEMISTRY

A number of important changes were found in blood chemistry after surgical duodenal drainage had been performed. No differences, however, were revealed between the group which received histidine and that which did not.

Determinations of the total serum electrolyte pattern were done on two dogs approximately two months after operation. The results are given in Table II. One animal (No. 4) was a control and was sacrificed on the day that these determinations were done and shown to have a perforated ulcer of the jejunum walled off by adhesions. The other dog (No. 14) had received daily injections of histidine. This animal died of acute intestinal obstruction five days after the blood studies were done and had a small superficial erosion of the first portion of the jejunum. Symptoms of the acute obstruction did not become apparent until about 12 hours before death.

A change in the distribution of the anions had occurred in both of these animals. Comparison of the findings with the normal figures for dogs, published by Atchley and Benedict (6) shows that a marked decrease in serum protein and bicarbonate content had occurred. This change had been compensated for by an increase in serum chloride. The values for total acid and total base fell within the lower limits of normal. The distribution of sodium and potassium was within normal limits but the calcium was somewhat low in one animal. Total base was estimated by adding two milli-equivalents for undetermined magnesium. Calculation gives normal values for undetermined anions (sulphate and organic acid). The total serum cholesterol was also determined on the same animals and found to be rather low in both of them.

The fall in serum protein was followed at intervals in a number of animals (see Table III). The values obtained before operation varied between 5.1 and 6.6 grams per cent. A fall was detected shortly after operation and continued gradually and progressively throughout the course. Terminal values were obtained within two weeks of death in four dogs (excluding dog No. 14 which died accidentally) and varied between 3.4 and 3.7 grams per cent.

Partitions of serum protein were done on three occasions shortly before death of the animal. The figures obtained were as follows:

Dog No.	*Day*	*Albumin*	*Globulin*
4	63	1.7	1.7
14	51	1.9	2.3
5	78	2.6	1.5

These figures show that the decrease in serum protein had occurred in both the albumin and globulin fractions although it was greater in the albumin fraction.

Total blood amino nitrogen was studied before operation in six dogs and after operation in ten dogs. Repeated determinations shown in Table III on animals No. 4 and No. 5 before operation revealed wide fluctuations in the normal "fasting" values in the same animal. The range of normal values occurring in 12 observations on these and four other dogs extended from 8.7 to 13.7 mgs. per cent of amino nitrogen. Twenty-seven determinations were made on 10 dogs at various intervals after operation, with results varying between 6.7 and 11.3 mgs. per cent. The fluctuations found in individual animals were of the same degree as before operation and no consistent downward trend was observed. It was of interest, however, that in eight of the ten dogs, the blood amino nitrogen fell below the lowest ante-operative value of 8.7 mgs. per cent at some time during the post-operative period. No difference was found between the values obtained in the control animals and in the animals receiving histidine injections.

TABLE II

Serum Electrolyte Partition After Operation of Surgical Duodenal Drainage

Control	Non-Protein N mg. per 100 c.c.	Sodium	Potassium	Calcium	Chloride	Bicarbonate	Phosphate	Protein	Total Base	Total Acid	B—A	Cholesterol mg. per 100 c.c.
Dog No. 4 63 days after operation	35	143.8	4.7	3.9	118.7	19.4	2.5	7.9	154.4	148.5	5.9	132
Dog. No. 14 51 days after operation (received histidine)	20	143.7	5.0	4.7	121.5	15.5	2.5	9.8	155.4	149.3	6.1	120

All figures except serum cholesterol and N. P. N. are expressed in milliequivalents per liter. The total base is calculated by assuming two milliequivalents for the undetermined blood magnesium

HYDROCHLORIC ACID SECRETION

Twenty-three test meals were done before operation in six dogs and the free acidity was found to vary between 0 and 40. Repeated observations on individual animals gave fluctuating results (see animals No. 4 and No. 5 in Table III). Thirty post-operative determinations were made on eight animals and again variable results were obtained ranging from 0 to 36 degrees of free acidity. It was clear, however, that no tendency to an increase in the concentration of hydrochloric acid in the stomach after a broth meal

TABLE III

Serum protein, total blood amino nitrogen and acid secretion in dogs before and after surgical duodenal drainage. Dogs No. 4 and No. 5 were control animals (see text). Number 18 and 19 died shortly after operation. The remaining animals received histidine.

Dog No.	Serum protein gm. per 100 c.c.		Amino nitrogen mg. per 100 c.c.		Test meal	Free Acid	Total acid

was present after the operation. On the contrary, there was a terminal decrease in gastric acidity. The final test meals done within two weeks of death in seven animals gave very low values for free acid. Five were anacid and two were five and six degrees respectively. The fact that the samples were usually contaminated with jejunal contents or with food residue even after 24 hours of starvation in these animals with marked cachexia, deserves mention. No difference between the gastric acidity of animals receiving histidine and controls was apparent.

TISSUE AMINO NITROGEN

In view of the possibility that histidine might exercise a protective effect against jejunal ulcer by some mechanism involving a local increase in tissue amino nitrogen, determinations of the latter were made on a few animals. The amino nitrogen content of the proximal jejunum and antral portion of the stomach was

studied in two normal dogs, two dogs of the group receiving histidine and one of the controls. The results are given in Table IV. No significant differences were present.

DEVELOPMENT OF ANEMIA

Repeated blood counts were done on two controls and five animals receiving histidine. All of the animals developed a progressive secondary anemia. This anemia was as marked in the group which received histidine as in the controls. No important changes were found in the total and differential white blood counts.

TABLE IV

Tissue Content of Amino-Nitrogen (mg./gm. of tissue). Duplicate specimens of the antral portion of the stomach and upper jejunum in five dogs, three of which had undergone surgical doudenal drainage. Dogs No. 11 and 15 received histidine and Dog No. 4 did not

PATHOLOGICAL FINDINGS

At autopsy there was a marked decrease in the amount of subcutaneous and omental fat. In some instances, the liver appeared fatty. Submucosal hemorrhages were frequently found in the small intestine and to a less extent in the colon. At times the villi of the upper jejunum appeared shrunken and the surface of the intestine had lost its normal velvety appearance. A few superficial erosions of the antral portion of the stomach were present in three animals. Unusual prominence of the rugae of the fundus of the stomach was seen only twice. There were no other gross manifestations of "gastritis." Edema of some of the abdominal organs, particularly of the stomach and intestine was present in two animals. One of them also had marked ascites and slight hydropericardium and hydrothorax. Dependent edema was never observed.

Microscopic: Sections of the ulcers showed loss of mucosa and at least part of the muscularis, the base of the lesion being covered with a polymorphonuclear exudate and fibrin which in the majority of instances overlay a layer of fibrous and granulatous tissue. The vessels in the base of the ulcer were normal except in two specimens where thrombosis with recanalization had occurred. The mucosa adjacent to the ulcers showed edema, and increase in the number of wandering cells present in the stroma. Fibrosis in the wall of the jejunum was never found beyond a short distance from the bed of the ulcer.

The antral and fundic portions of the stomachs were studied for histological evidence of gastritis. No increase in the number of wandering cells was found and collections of lymphocytes in the mucosa was rare. In some instances, there appeared to be an abnormal dilatation of the mouths of the glands in portions of both the fundus and antrum, with papillomatous projections of the mucosal surface, but it was difficult to estimate whether these findings exceeded the limits of normal variation. Goblet cells in the antral mucosa were few in number.

Sections of the jejunum and colon often showed a reduction in the height of the mucosal layer and a slight degree of atrophy of the muscularis. The atrophy of the jejunal mucosa was less marked in some of the dogs which received histidine than in the controls.

The majority of animals had fatty degeneration of the liver. This change involved the entire liver lobule in some dogs and only the central part of the liver lobule in others. Sections of the kidney showed the presence of large vacuoles in the cytoplasm of the convoluted tubules in some of the animals.

No pathological changes were found in the pancreas, spleen, adrenals, heart, thyroid or parathyroid.

DISCUSSION

These experiments demonstrate that surgical duodenal drainage, in addition to causing jejunal ulcer, results in many other profound changes in the animal, including gradual inanition, alteration in the serum electrolyte pattern with a fall in serum protein, some tendency to a decrease in the blood amino nitrogen, late gastric subacidity, secondary anemia and degenerative changes in the liver, kidneys and other organs. The administration of histidine had no effect upon these changes except that the incidence of jejunal ulcers in the dogs which received histidine was rather low, five out of a group of eleven showing no ulceration. Our results are at variance with those of Weiss and Aron who report complete protection against the formation of ulcers by histidine injection. This is probably due to the fact that our dogs were permitted to survive until moribund whereas their animals were sacrificed after shorter periods of time.

Histidine administration did not cause any increase in the amino nitrogen content of the ulcer bearing tissues, *viz.*, the antrum and jejunum nor in the fasting blood amino nitrogen level. Histologically, however, many of the treated dogs showed less atrophy of the jejunal mucosa than did the controls.

The question of the mechanism underlying the blood and other tissue changes in dogs with surgical duodenal drainage arises. Fatty degeneration of the liver and atrophy of portions of the gastro-intestinal tract are known to occur in prolonged starvation (8) and are probably part of the general picture of cachexia in these animals. It is also possible that drainage of duodenal juice into the terminal ileum is associated with a loss of some of the constitutents of these juices due to incomplete reabsorption and that a condition similar to a pancreatic fistula is produced. In these circumstances, the fatty degeneration of the liver might be analogous to that described in dogs with pancreatic fistulae and pancreatectomy (9).

The fall in serum protein in our animals was similar in rate to that found by Weech, Goettsch and Reeves (10) for dogs maintained on a deficient protein diet. It differs, however, in that it usually did not fall low enough to produce edema. Weech (11), furthermore, found that approximately one-fourth of his dogs on a low protein diet develop peptic ulcers. These facts suggest that surgical duodenal drainage may result in incomplete digestion or absorption of protein con-

Blood counts on seven animals with the operation of surgical duodenal drainage. Animals No. 4 and No. 5 were controls. The others received histidine. The initial blood count was taken before operation in each instance. All animals developed a secondary anemia.

stituents of the food because of exclusion of the bile and pancreatic juice from the upper gastro-intestinal tract.

The decrease in serum bicarbonate after surgical duodenal drainage may be due to a loss of bicarbonate from the outpouring of duodenal contents into the distal part of the intestinal tract where it may be incompletely reabsorbed. It is interesting that this change takes place without a coincidental fall in total base, suggesting that the cations in the duodenal juice are reabsorbed more readily than the bicarbonate. The rise in serum chloride compensates for the fall in serum protein and bicarbonate.

The tendency to a low serum cholesterol is apparently analogous to the decrease which takes place in prolonged starvation (12). The low values for blood amino nitrogen cannot be accounted for in this way, however, since Van Slyke found no diminution in the blood amino nitrogen of dogs after starvation (12).

The secondary anemia of dogs with surgical duodenal drainage might also be accounted for on the basis of partial inanition or possibly impairment of reabsorption of biliary pigments.

The study of the effect of diversion of duodenal juices by operation on gastric acidity suffers from the same handicap which impedes all study of the secretion of the total stomach when it is open at both ends. The normal range of variation in acid concentration is so wide that marked and fairly constant differences must occur under the conditions of a given experiment in order that their significance shall become manifest. The importance of duodenal regurgitation in the regulation of the level of gastric acidity is a subject of controversy at the present time (13, 14). In our own observations, in which only the chemical phase and not the cephalic phase of gastric secretion was studied by means of a weak broth stimulus, no evidence for rise in gastric acidity after elimination of the duodenal juice was found. McCann (3) also found no increase in gastric acidity in response to a meat meal after this type of operation. In our experiments there appeared to be a decrease in acid concentration in the stomach in the last two weeks of life. This might be interpreted as due in some way to the development of cachexia.

The importance of protein deficiency as a factor in the production of peptic ulcer is demonstrated not only by our findings in animals with surgical duodenal drainage but also in other types of experimentation. For example, Hoelzel and Da Costa (15) and others have produced ulcerations in the stomach of the rat on a low protein diet and Rassers (16) and Weech

have observed peptic ulcers in dogs which were fed on diets characterized by protein deficiency. There is, however, no evidence at present of a deficiency in protein metabolism underlying peptic ulcer in human beings.

CONCLUSIONS

1. Surgical duodenal drainage in addition to producing jejunal ulcers causes many other pathological changes in the dog.

(a) Marked cachexia develops.

(b) Changes in the electrolyte pattern occur, including chiefly a fall in serum protein and serum bicarbonate and a rise in serum chloride.

(c) The blood amino nitrogen is variable but tends to be lower after the operation.

(d) A marked secondary anemia develops.

(e) No increase in gastric acidity in response to a broth meal occurs. A decrease in acidity was found during the last two weeks of life.

2. Six of eleven dogs receiving daily injections of histidine monohydrochloride after surgical duodenal drainage developed ulcers. Five controls not receiving histidine all developed ulcers.

3. The administration of histidine did not influence the other physiological and pathological changes described.

4. The administration of histidine did not affect the amino nitrogen content of the jejunum or antral portion of the stomach.

Note: The authors are indebted to Miss Anne Barman for the serum protein determinations and Mrs. Mildred Watts for the blood counts. The histidine monohydrochloride used in these experiments was kindly supplied by Hoffmann-LaRoche, Inc.

SECTION VII—*Surgery of the Lower Colon and Rectum*

The Present Status of Radiation Therapy in Carcinoma of the Anus, Rectum and Sigmoid Colon*

HARRY E. BACON, M.D., F.A.C.S.
PHILADELPHIA, PENNSYLVANIA

EXPERIENCE has shown that no single method of treatment is suitable for all cases of cancer involving the anus, rectum and sigmoid colon. Although surgery should be considered first, it behooves us to regard irradiation as an addition to the armamentarium for the eradication of this disease. The recent advance in the therapeutic use of radium and roentgen rays is a convincing proof that this method is of value, especially with the improved technique, increased voltage of present-day installations and better selection of cases.

As is known, the therapeutic activity of radium is due to disintegration of the radium atom, by which are produced a series of different radiations, substances and emanations. It has been shown that normal and pathologic tissues are affected by radioactive substances, although the embryonic or immature cells are less resistant than normal calls (8). By the same token, the squamous epithelium of the anus is more resistant to radiation than is the mucous membrane of the rectum and sigmoid colon.

Irradiation, which combines the use of radium and X-rays, may be employed alone or in conjunction with surgery. In either instance the treatment should be selective, since irradiation is not applicable in all cases. The determining factors, and, of course, the results, will depend upon the physical condition and age of the patient, the size and location of the cancer,

*Read before the Proctologic Society of the Graduate Hospital, University of Pennsylvania, November 20, 1935.
Submitted February 24, 1936.

whether at the anus, low in the rectal ampulla, or in the sigmoid; the grade of malignancy and its radiosensitivity; the structures invaded and extent of metastasis (3).

Opinions differ as to the value of radiation therapy before and after operation. May (17) advocates the use of roentgen rays pre-operatively and post-operatively, and employs them routinely. Larson (14) believes that large, inoperable growths may sometimes be rendered operable by these rays, and Schmieden (21) considers this to be occasionally true even though metastasis to the liver has occurred. Binkley favors the interstitial implantation of radon seeds at the time of or immediately following operation, and external radiation at a later date. Yeomans (23) prefers exposure of roentgen rays through six portals of entry, each being treated three times in periods of 30 minutes each, the course to be repeated in six to twelve weeks. Bowing (7) believes that more aggressive radium treatment, followed, after a lengthy interval, by surgical excision, is the procedure in cases presenting themselves reasonably early. He distributes platinum-filtered needles (1 mg.) evenly throughout small growths for 48 hours, or gold radon seeds. In other cases, he employs "contact treatment": two or three radon tubes strapped side by side with adhesive tape so as to form a plaque. The tubes are introduced through the proctoscope against the growth, the normal bowel wall being packed away with gauze soaked in metaphen. A dosage of 60 to 100 mg. hours per square centimeter of malignant tissue is given. This is repeated daily until the entire lesion has been covered.

Fitzwilliams (9) favors a preliminary colostomy and the intratumoral insertion of radium both through the lower loop of the colostomy opening and through the rectum. Four to six weeks after the colostomy is performed, a narrow sigmoidoscope is introduced into the lower bowel loop until the growth is visualized. He inserts a well-protected tube containing 30 mg. of radium into the growth, which is allowed to remain in place for four to five hours. The following day the growth is approached through the anus, with the same dosage and for the same length of time. After a rest of one day, the entire procedure is repeated. Approximately 500 mg. hours of radiation are given directly into the growth. Three courses similar to this are given at intervals of one month. Quick (20) employs a combination of buried emanation, filtered radium internally and externally, and surgical exposure if necessary. For annular growths, he uses 0.5 mm. platinum tubes arranged end-to-end in a small rubber tube which, in turn, is encased in a larger rectal tube. In this way, he has been able to use 500 mg. hours per tube without danger of reaction. Where the tumor is confined to one portion of the rectal wall, he advocates a bougie of solid rubber with platinum tubes in its grooves. Kelly and Ward (14) advise implantation of radon seeds into the growth through a proctoscope. According to their calculations, 1 mc. of radium emanation is sufficient to destroy 1 c.c. of the tumor tissue. Others vary their treatment according to the type of growth; for example, in cancerous stricture of the rectum, Yeomans (22) inserts tubes in tandem of rubber within the lumen. For papillary growths, Jones (13) distributes needles or emanation tubes throughout the tumor and uses a flat oval applicator containing the radium tubes for large, flat, ulcerating lesions. Interstitial irradiation following surgical approach, as devised by Newman and Coryn (18), has been found unsatisfactory by Gabriel (10), who employed the procedure in a series of 89 cases.

Binkley (5), whose experience has been vast in treating anorectal malignancy, remarks that "besides being used as a palliative means in inoperable cases, radiation therapy is capable of producing clinical cures in properly selected, favorable and operable cases." He suggests three distinct groups of cases in which radiation therapy may be employed advantageously: (a) "Favorable and operable cases in which one may expect a clinical cure by this method alone. The tumor, however, must lend itself to interstitial radiation (4); (b) Operable cases in which pre-operative radiation therapy offers advantages in promoting clinical cures; (c) Advanced cases in which radiation therapy, either alone or combined with colostomy, offers the highest degree of palliation." For the favorable group, the first step is external radiation. He uses approximately 900 roentgens through six portals of entry and a perineal field when the growth is in the lower rectum on alternate days. In some cases he employs a 4 gm. radium pack, 8000 mg. hours at 15 cm. from the skin daily; whereas, in others, both forms of rays are utilized. In this case, the roentgen rays are administered to each part with a dosage of a little below the erythema. The radium rays are then given through two to four portals, with a dosage of about 50,000 mg. hours at each portal. Binkley (1) mentions that external radiation is followed by beneficial results in most cases; bleeding is lessened, ulceration is decreased, the tumor becomes smaller, and the degree of mobility is increased. Improvement in the general condition of the patient, with increase in weight and strength, is frequently noted. As a second step, gold filtered emanation seeds are implanted two weeks after completion of the external radiation, the dosage varying from 10 to 75 mc., according to the size of the tumor.

His technique may be described as follows: A proctoscope of suitable length, with an oblique distal opening, is introduced to the upper level of the growth. Under direct vision, the seeds are inserted into the upper portion of the tumor by means of a fishhook needle. These seeds are placed approximately 1 cm. from each other. The proctoscope is slightly withdrawn, at which point another row of seeds is inserted, which procedure is repeated until the entire growth has been treated with the required number. In the advanced, but still favorable, cases, he finds that a colostomy is often required to relieve the partial obstructions. This is performed either before the external radiation or in the period between it and the interstitial application. If the colostomy is so constructed that the gut between the lower opening and the growth is short and without undue tension (6), a sigmoidoscope may be introduced through the lower loop and seeds inserted directly into the tumor.

Where radical surgery is to be combined with irradiation, Binkley employs external therapy alone in cases where adequate dosage of radon cannot be given or when the growth is situated above the peritoneal reflection. A full erythema dose is given through each of six portals three weeks before operation. He uses external and interstitial irradiation as follows: in

perineal resection, a full erythema dose of external irradiation is given, followed by a colostomy in three weeks. After a lapse of one week, gold seeds are implanted and the resection is performed seven to ten days later. In the one stage abdomino-perineal resection, external radiation is given primarily and followed three weeks later by the interstitial insertion of gold seeds. The operation is performed one to two weeks later.

In the advanced cases, he employs external irradiation in sufficient intensity to restrain the activity of the growth. Here ¾ to 1 erythema dose of high voltage roentgen ray is given through each of six portals, in one or two applications, with treatments daily or on alternate days. It does not damage the skin and may be repeated at one or two month intervals. He remarks (3): "Irradiation usually offers the inoperable patient much greater palliation, without the possibility of an immediate fatality, than that provided by incomplete removals."

So far as trans-peritoneal radiation for growths above the peritoneal reflection is concerned, it should be mentioned that Gordon-Watson (12) obtained discouraging results using this method.

It is generally conceded that epithelioma of the anus responds well to treatment with radium because of its accessibility. Mummery (16), as a matter of fact, prefers it to excision, and remarks: "the results of radium treatment are better than those obtained by operation." Pruitt (19) reports good results in these squamous cell carcinomata by inserting needles containing 1.33 mg. of radium into and around the growth, including the ischiorectal fossa. The needles are left *in situ* four to six days, or until a dose of 2000 to 4000 mg. hours is given. In addition, external radiation is given over the sacrum, perineum and inguinal regions by the application of columbia paste containing the needles. In this way, approximately 9000 mg. hours are administered posteriorly and 7000 mg. hours anteriorly over each inguinal region. Souttar (22) employs a moulded apparatus containing 120 to 160 mg. of radium, and applies it for 15 to 18 days. The inguinal glands on each side receive a similar application. Binkley (2), however, advises external radiation of high voltage roentgen rays and radium rays, to be followed by the interstitial implantation of gold filtered emanation seeds. In some cases irradiation may be combined with surgery, as advocated by Yeomans. Here radon capillaries are inserted into the tumor, followed by radical excision in two to four weeks. In a general way it may be said that anal epitheliomata will respond well to interstitial radiation, combined, in some cases, with external radiation. Gordon-Watson (11) believes that if deep infiltration of the ischiorectal fossa, adjacent tissues, or invasion of the inguinal gland has not occurred, an immediate cure may be anticipated with this method.

From the several procedures described, it is clearly obvious that the surgical approach and the use of radium and X-ray, their dosage, screenage and time of application differ markedly with various workers. Yet, even though certain methods have proved unsatisfactory in many cases, are we justified in condemning the use of irradiation as a therapeutic measure?

During the past several months it has been my privilege to review meticulously the records of 500-odd cases of carcinoma of the anus, rectum and colon, nearly all of which had come to necropsy; tissue sections being made in almost every instance. In this study it was appalling to note that in the vast majority of cases, radical surgery or palliative colostomy having been performed, subsequent irradiation had not been employed; yet, on the autopsy table, recurrence and metastasis to various structures were observed.

Just how much radiation therapy would have inhibited the growth is a matter of conjecture, but it is in our power to realize that these cases were not extended the privilege of what radiation therapy might have accomplished. According to one writer, approximately one-half the patients who are subjected to radical extirpation die of cancer. If such is true, postoperative irradiation should be advocated to prevent recurrence. In view of the fact that some investigators have obtained good and favorable results and, in some cases, cures, should not we, as proctologists, with the aid of the radiologist, give the unfortunate patient the opportunity of benefiting by what science has revealed, even though we be keenly appreciative of its limitations? Certainly the combined use of surgery and irradiation should greatly reduce the high mortality as it exists at the present time.

Annual Abstracts of Proctologic Literature

(May, 1934-May, 1935) By CLEMENT L. MARTIN, M.D., Chicago, Illinois

The complete bibliography from which these Abstracts were made will be published in full in the Transactions of the American Proctologic Society, 1935.

FISTULA IN ANO

N. D. Smith advises delay in incising the abscess until there is definite fluctuation: "incision is indicated as soon as the abscess points or when there is definite superficial fluctuation." Many may not agree with this view. He states that a common practice, that of inserting gauze-strip packing is painful and of doubtful value; on this there will be more general agreement.

Murdoch saves as much as possible of the external sphincter where the fistulous tract crosses it. "Several years ago I began saving the continuity of considerable sphincter muscle at the site of fistulectomy." "A slight amount of freeing of the bowel wall above is done. It is then possible to place the sphincter upward and stitch the rectal wall downward over it fixing the sphincter against solid tissue in a somewhat higher but nevertheless good functioning position. The final result is a more normal anal contour without as much notched defect, this is sometimes marked after the usual operation."

This technic is applicable to about 40% of his cases, in the others the usual fistulectomy is performed.

Allen & Haskell used a two-stage fistulectomy in 119 of 226 cases. This is extending a sometimes necessary procedure beyond what most proctologists will regard as its indication.

HISTORY

Although the name of Bodenhamer crops up every now and then as one reads the literature of rectal disease few of our generation have more than a vague notion of his character or accomplishments. *Kleiner's* sketch of his life indicates that he was forceful and aggressive but selfish and not over-burdened by a regard for medical ethics, that he was capable, a student, and that his publications helped to advance the study of proctology.

INJURIES

Nightingale had a case of rupture of the sigmoid from compressed air. Unlike most of the cases, the nozzle of the air hose was not brought in contact with the anus by a practical joker. The workman was using the air to clean his clothes and accidentally touched the anus. There were several tears of bowel wall too, but none through the serosa. Recovery followed laparotomy and repair of the bowel.

Black & Weisman in 1926 reported 27 cases, 19 of them fatal.

La Croix & Ryan cite the case of a farmer who suffered a common cause of rectal injury—that of impalement. This man slid down a load of hay causing the pitchfork handle, about 2 inches in diameter, to enter and lacerate the anus, rectum and sigmoid. The handle entered the bowel to a distance of 14 inches. He removed it himself. At operation a 6 inch rent in the sigmoid was found, most of the tear being in the mucosa, a relatively small portion through the serosa; a 3 inch laceration in the mesocolon was present. Recovery followed.

Epstein attended at the Lincoln Hospital a man who had inserted two apples in the rectum and who had at various times previously used a cucumber and parsnip in the same manner. On entry the patient had a 2" tear in the recto-sigmoid, localized peritonitis, and free soapsuds in the abdomen. Trauma from efforts at removal and a soapsuds enema explained these. The tear in the recto-sigmoid was not seen proctoscopically although the instrument was passed beyond its site. The star shaped appearance at the center of the apple, as seen in the roentgenogram, was a point of interest. The patient recovered.

INFLAMMATIONS

Several articles reveal the importance of the colon and rectum as foci infection. *Hirschmann's* discussion of the subject is definitely informative.

An unusual type of chronic buccal and peri-anal ulceration is described by *Wiseman* in which diagnosis was impossible and therapy of little avail. *Preusser* emphasizes the importance of anal infection in an article treating of the general phases of the subject.

INSTRUMENTS

Bacon has devised a self-retaining illuminated proctoscope that is a short instrument tapering from the base to an expanded portion at the end, this expanded portion being grasped by the sphincter holds the instrument in place. It can also be used with a light adaptor, thus making it more generally available. He has also devised a stricturoscope consisting of a set of five tubes varying in calibre from ½" to ⅛". By means of these the stricture can be calibrated, dilated, or treated before medicaments are applied. It is illuminated and has an adjustable lens which may be swung into place as desired.

INTRAPERITONEAL VACCINATION

Steinberg & Goldblatt (see 1934 Transactions) found that the injection of heat-killed *B. coli* suspended in a saline solution and injected into the abdominal cavity, decreased the incidence of peritonitis after operation.

Hermann determined that a mixture of streptococci and *B. coli* was more effective than *B. coli* alone.

The former investigators advocate the use of a single intraperitoneal injection of 30 c.c. of 1% gum tragacanth in normal saline solution containing about 200 million heat-killed *B. coli* per cubic centimeter. (Coli-bactragen).

Following Hermann's and Steinberg's work, the use of a vaccine containing both *B. coli* and streptococci was started 8 years ago at the Mayo Clinic and a marked reduction in mortality reported from its use by Rankin and Bargen. This group continues its pre-operative use in colon cases. Some unfavorable reactions following its use have been reported. (See 1934 Transactions, Intraperitoneal Vaccination, Jones' discussion).

Potter's and Coller's experience has been favorable with Coli-bactragen (Steinberg) in 79 cases.

Gundel & Suessbrich have treated 240 cases of peritonitis with "peritoneal serum" and have studied the cases bacteriologically. They used a polyvalent serum containing colon bacillus, gas-gangrene bacillus, and enterococci. They state that of 51 patients given this serum for prophylaxis or treatment, 6 died but 5 of these had heart or lung complications.

Young & Marks have used amniotic fluid concentrate in a series of 48 cases of colon resection with a mortality of only 2% in the whole group. They regard the beneficial effects of vaccines to be non-specific. A preparation of amniotic fluid is now on the market; it is named Amfetin.

SECTION VIII—*Editorial*

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastroenterological Association is in no way responsible for editorial expressions.

WHAT IS AN "INTRACTABLE" PEPTIC ULCER?

FOR several years the medical profession in general has been bombarded with literature about the treatment of "intractable peptic ulcer." The pharmaceutical houses have awakened to the fact that peptic ulcer is a common disease and that there is money in advertising drugs offered as a "cure" for it. Pressure has been brought to bear on research workers in universities to produce some specific substance which would cure an ulcer, so that the substance could be patented and could become a source of income for the university comparable with insulin and vitamin D.

General practitioners, and unfortunately many specialists also, feeling the pinch of the depression, have welcomed the opportunity of giving intravenous treatment twice a week or more, thus adding materially to their incomes, and others, apparently with similar intentions, have devised new methods of treatment requiring either continuous bed or hospital care or frequent office visits. And some surgeons (or let us rather call the type I am referring to, "operators") who had begun to see that operations for simple ulcer were being frowned upon as unnecessary, have seized upon the term "intractable ulcer" as an excuse for the performance of new, more radical operations in greater numbers. We hardly ever see an ulcer patient today who has not been through one or more of these newer tortures.

Now what is this bugaboo "intractable ulcer," that has so suddenly been raised to frighten medical practitioners? Feeling that perhaps our unfamiliarity with the subject might be due to our seeing only "easy" cases in private work, and realizing that the more severe and previously neglected cases would be found in the hospital, we have been asking our internes if they could tell us how many "intractable" cases they have seen. They have looked puzzled and have asked us what we meant, stating that the uncomplicated cases they have seen have all been very tractable. Our colleagues concur in this opinion.

From a study of histories of long-standing ulcer cases, one must come to the inevitable conclusion that each attack of ulcer symptoms is self-limiting, and not very differently influenced by vastly different modes of treatment or in fact an entire lack of treatment. Cole has demonstrated conclusively that each attack represents the development and complete healing of a separate and distinct ulcer, with subsequent ulcers often occurring at considerable distances from the previous ones. We have been able to confirm his observations roentgenographically, and pathologists have discovered multiple ulcer scars in the stomach and duodenum of patients with histories of many attacks of ulcer symptoms. The only logical inference to be drawn from these facts is that a peptic ulcer is an acute lesion, healing spontaneously and completely in a comparatively short time, and persisting or becoming chronic only as a result of the development of complications. The three marked complications of acute perforation, hemorrhage and stenosis are comparatively easy to recognize and their treatment is becoming standardized. The less acute but severely disabling "slow" perforations or near-perforations or the more or less acute complications in contiguous organs like the gall bladder or pancreas, resulting in deforming adhesions, scars, indurations or even abscesses or cysts are not so generally recognized. These, together with reflex or retrostaltic symptoms resulting from diseases of more distant organs, or entirely distinct symptoms from allergic, endocrine or nervous causes, as well as the occasional cases of carcinomatous degeneration, constitute the principal reasons for "intractable" symptoms.

Is it not therefore unreasonable, when a patient has symptoms which fail to be relieved by the usual measures found to be successful in ulcer cases, simply to call them "intractable" and institute treatment, medical or surgical, without first exhausting every effort to find out the reason for this intractability? In our experience such an investigation will invariably disclose a definite cause for the persistence of symptoms and will result in an intelligent medical or surgical attack upon the underlying causes. It is safest and most scientific, in the long run, to adopt the slogan "An intractable ulcer is a complicated ulcer."

Albert F. R. Andresen, Brooklyn.

SECTION IX—*Book Reviews*

(This section is open to contributions from any medical reader, whether or not a member of the Editorial Council).

Exploration Radiologique des Colons et de l'Appendice, Au Moyen des Solutions Floculantes; Images de Muqueuses, by Drs. Gorges Maingot, (Electro-radiologist, Laennec Hospital), Raymond Sarasin (former assistant in the Geneva and the Zurich Hospitals) and Henri Duclos (Assistant in Radiology, Laennec Hospital), with a preface by Dr. Antoine Béclère, (Head of the Medical Section, Academy of Medicine, Paris); Published 1935, by Masson & Company, Paris, 230 large, Atlas-style pages; price 200 francs.

THIS is the seventh of the series of monumental, epoch-making volumes concerned with Roentgen studies of special sections of the body, which recently have made the medical profession of the world indebted to its French colleagues and, peculiarly, to those audacious, yet understanding, publishers, Masson and Company. We say "audacious" because, so far as we have observed, no concern other than Masson & Company, has had the vision and the courage to comprehend the real need for authoritative atlases covering methods and results of skilled Roentgenography of the major body-systems and then has exhibited the patience, technical facilities and the artistic appreciation, requisite for carrying through to unrivalled fulfillment so extensive a plan. For, assuredly, as one handles and familiarizes himself with the individual volumes of this superb series, he cannot help but feel that, at the prices at which the books are sold, Masson & Company disregarded the ideas of *money-profit when they conceived and executed their* task. Rather, the work must have been inspired by a keen sense of our profession's need. Whatever may be the publication costs, the actual carrying through of the enterprise has been truly a "labor of love."

When we reviewed the two volumes which dealt with Roentgen studies of the Oesophagus, Stomach and Duodenum (*American Journal of Digestive Diseases and Nutrition*, Vol. 2, No. 6, Aug., 1935, p. 382) we expressed our sincere admiration for this series of special monographs and declared that the Roentgenologists of the world could not consider their educations completed unless they had been fortunate and had visited the Roentgen laboratories of Paris, or if that were impossible, they now had on their library shelves, the atlases published by Masson & Company. Our opinion has been supported by those who, recently, have sojourned in France and by those American clinicians and radiologists who have secured the volumes which previously we reviewed. In a sad situation are those who have availed themselves of neither opportunity!

Inspection of this, the most recent atlas, demonstrates that Drs. Maingot, Sarasin and Duclos have maintained the high, general standard of endeavor established by the Authors of the monographs which earlier were issued. For, in the Roentgen study of the colon, the appendix neighborhood and the appendix itself, they have set a mark which rarely will be approached; surpassed, we believe, never. Above all, in their discussions, constantly is emphasized that *clinical* radiology, not *technical* radiology or picture-making alone, has guided their efforts. Professor Béclère's "Preface" well puts it: *"Ce livre est l'oeuvre de trois medicins, excellents radiologistes!"* Would that, universally, it were recognized (and practiced!) that radiologists first must be trained physicians; technicians and light-and-shade interpreters only incidentally! In pathology, it does not necessarily follow that he who brings to the microscope's stage the most beautiful slides, must be the ablest histopathologist. Unfortunately, Roentgenology often seems to follow the positive, but wholly inaccurate and limiting, approach, that the making of striking films constitutes the goal of the radiologist. If nothing more, these atlases sent forth by our French colleagues, illustrate the new agenda of Roentgenography, viz. the *purposeful* exposure of subjects; the individualization of radiologic effort in the attempt to elucidate problems which history and clinical and laboratory examinations have suggested. This is far different, indeed, from submitting every subject to a routine formula of examination—be it suited or unsuited—and then endeavoring to *specialize* the interpretation. Such is a fundamental advance in making radiology an important adjunct to the physician's diagnostic armamentorium.

This volume dealing with Roentgen examination and interpretation of colon and appendix lesions, emphasizes the data which may be secured by the "triple-film" method. Prof. Forssell, Stockholm, pioneered the mode of Roentgen study of viscera whereby information was not limited alone to observations concerning contour, motor activity, changes in position, etc., but where definite manoeuvers were instituted with the object of demonstrating, Roentgenologically, abnormalities in or arising from the mucosa. That Forssell contributed a distinct addition to radiologic diagnosis, amply has been proved by the numerous studies recorded with respect lesions of the oesophagus, stomach and duodenum. In these viscera, Roentgen examination cannot be considered complete unless Forssell's technique has been exhibited and its results have been appraised by one expert in interpretation. Indeed, Forssell has given to the radiologist a method of diagnosis which enables him with regards oesophagus and stomach in a vast number of instances, to anticipate the data supplied by the gastroscopist—and this at little expense or risk to the patient. Not that Forssell's method ever will wholly supplant gastroscopy, but, undoubtedly, in numerous instances, it will give information respecting the condition of the gastric mucosa which is quite as dependable, from the clinical aspect, as is that supplied by even experts in gastroscopy.

Drs. Maingot, Sarasin and Duclos detail simply and completely the "new" radiology in respect the colon. In a series of quite normal subjects they enable us to compare and contrast the Roentgenograms secured after (1)—opaque enemata of 400-500 c.c. of a 12% solution of thorium-oxide suspension; (2)—evacuation of the opaque medium, and (3)—mucosal patterns after insufflation of the opaque substance. They exhibit illustrations of the special contrivances which facilitate introduction of the opaque medium and which enables the operator to perform adequate insufflation of the distended colon following evacuation of the primary opaque enema. Formulae of opaque media are given and cautions in respect types of case not suited to the procedure are listed. By easy stages, but not in kindergarden lessons, the reader is led from consideration of Roentgenograms which are those of normal persons to such as may be secured from subjects affected with various pathologic lesions.

There is introduced a very thorough, and withal, unique chapter graphically portraying the physiologic activities peculiar to the musculature of the colon and the effects which normal and abnormal responses produce Roentgenographically. The various "patterns" which are derived, together with their interpretations chemically, do much to familiarize the observer with the changes in such patterns, Roentgenographically where disease is present. The text which accompanies

these basic demonstrations is clear, crisp and informative.

However, much as the Authors rely upon changes in contour, tone, position, retention or in rapidity of evacuation of the colon as a whole or of special parts as exhibited radiologically, the chief endeavour of the book is directed towards exhibition of mucosal appearance when an opaque medium is "sprayed" upon it after the enema has been evacuated. These "relief" Roentgenograms, in subjects without or with, organic disease permit the production of striking films. Such films are by no means simply unique or curious technical achivements: in many instances, they demonstrate mucosal lesions wholly impossible to suspect or to prove in patients harboring no gross or deforming disease. When contour or position of the colon is changed by demonstrable affections, in addition to aiding in the better proof and localization of such, these "relief" films, often quite astonishingly, permit exhibition of the vast degree of associated mucosal change. The films submitted to demonstrate the wide variety of mucosal abnormalities, technically, are superb. Most striking "reliefs" and alterations in muscular action are exhibited subsequent to gaseous distention of the gut and then insufflation of opaque media and colon collapse upon evacuation of enemata. Indeed, only by this "3-film" method of Roentgen study of the colon do the radiologist and the clinician obtain an adequate conception of bowel architecture and of associated mucosal abnormalities. Very often, in fact, the Roentgen study demonstrates that gross motor changes of the gut's wall are wholly due to alterations from the normal in the mucosa. A text is included which definitely and intelligently points the "accidental" or artefact type of film and emphasizes the need for cautious interpretation.

Part 3 of this treatise deals with true colon lesions as shown by the "3-film" method of study. An excellent text and illuminating films are presented detailing Roentgen observations in instances of "Colitis," non ulcerative and ulcerative, with and without mucosal deformity, "Sigmoiditis," (in syphilis, both the tubal fibrosis and the gummatous or tumor-types are considered); "Tumors," including polyposis,—malignant and benign—(very striking are the mucosal patterns accompanying multiple poylposis); "Diverticula," with and without associated inflammatory tissue response, (very remarkable films, revealing altogether unexpected defects in colon walls, especially when peridiverticulitis complicates the lesion); "Tumors Extrinsic to the Colon," but producing alterations in contour and function, and "Tuberculosis,"—in this lesion, it seems that the insufflation technique is of the very greatest significance in demonstrating mucosal involvement not in any way recognizable by the now ancient opaque enema method alone. Through this entire Section dealing with organic colon lesions, the discussions and manner of presentation of illustrative material in every way exemplifies that Drs. Maingot, Sarasin and Duclos are clinicians and not merely radiologic technicians. It has never before been this reviewer's privilege to observe so concise, yet so complete, clinical and Roentgenologic exhibition of data.

Section 4—concerns itself with the Appendix, as a radiologic problem. The Authors admit that, from 1909, when Béclère first demonstrated the appendix by the Roentgen method, despite the careful, conscientous work of numerous Continental and American investigators (the pioneer work of Case in the United States is credited), the true significance of its visualization by films, still remains unestablished. Certainly, it would seem, that in "Chronic Appendicitis" alone is there justification for attempting radiologic study of the affection—and such study, not alone to prove whether or no the appendix lumen is patent, but chiefly to demonstrate visceral position, size, its relation to other abdominal organs and its effects upon the function of the colon, stomach and duodenum. When sub-acute or acute appendix disease is suspected, the Roentgen method of examination is not justified because of attendant dangers from its exhibition. This admirable clinical position taken by the Authors wholly has been supported by radiologists in other important laboratories.

The Section considers demonstration of the appendix by the oral and the enema routes of introducing opaque substances into the hollow viscera. Each has its advantages with respect not only the showing of the appendix on the films but of giving opportunity for exhibiting Roentgenologic abnormalities in tissues which are neighbor to the appendix. Often, indeed, the alterations shown in peri- and para-appendicular structures are of significance far greater than is proof that the appendix can or cannot be visibilized or of its length, position, fixation, etc. In the average patient, greater information concerning the appendix itself will be secured from opaque enemata but more Roentgen data concerning neighboring structures will become evident by the oral administration of the opaque substance.

The Authors present numerous film-reproductions showing the various types of appendix, the ability of the "organ" completely or incompletely to fill and empty, appendicular peristalsis, local or general dilatations, unusual positions, kinks, twists and their effects, appendicular diverticula (not nearly so infrequent as has been considered), intralumen calculi, the effects of diseased or unusually placed appendix upon bowel peristalsis—irritation and atony. There is a rational, conservative discussion of the "appendix syndrome" and its meaning to the clinician.

Section 4 concludes by what the reviewer regards is a too brief consideration of pathologic lesions of the terminal ileum, in which lesions all too-frequently the appendix is diagnosed the offender and is removed only to be followed by a series of disturbances due to progressive pathology in the small gut. Although the Authors exhibit several films detailing terminal ileum lesions in association with appendix abnormalities, there is not the complete radiological or clinical consideration of "terminal," "regional" or "non-specific ulcerative ileitis" (Crohn's syndrome) now so urgently —at least, in the United States—demanding recognition, elucidation as to nature and, above all, adequate treatment. It may be that the Authors plan later to present a separate work in which the Roentgenologic method is applied to lesions of the small intestine and in such they will give an appropriate discussion of Crohn's and other extremely important infectious, ulcerative and non-ulcerative, ileal disease and its serious consequences. Be that as it may, inasmuch as the early clinical manifestations of Crohn's syndrome generally result in a wholly non-curative appendicectomy, an operation which not alone may prove futile

but which may be followed by disastrous consequences in some individuals, it appears to the reviewer that, in this discussion of the appendix, the Authors could have wisely introduced the abundant Roentgen evidence which for several years—certainly in the United States—has been available. The reviewer strongly feels that, particularly in young subjects, no closed opinion regarding subacute or acute appendicitis existing alone, is possible until the clinician has excluded from being present "non-specific" ulcerative ileitis and tuberculosis. And of the two last named, the problem of their differentiation, clinically and radiologically, is by no means simple. Certainly, Roentgenograms alone are inconclusive.

But the above criticism by no means detracts from the value of the atlas being reviewed, especially when one limits the review to the Roentgenologic value of the material discussed as covered by the book's title. The Authors have given us a remarkable radiologic presentation of a specified field of endeavor and have supplemented it with accurate and conservative clinical comment. Technically, they have exhibited, strikingly, the possibilities of the new "3-film" method of Roentgenographic examination. The reviewer never has met with so complete and so brilliant an *arbeit* in any language. The library of no radiologic laboratory, of no Roentgenologist, of no clinician—physician or surgeon—whose major labors are concerned with abdominal problems, can be considered adequate unless it includes this volume contributed by Drs. Maingot, Sarasin and Duclos.

Frank Smithies, M.D.

Medical Papers, dedicated to Henry Asbury Christian, Physician and Teacher, from his present and past associates and house officers at the Peter Bent Brigham Hospital, Boston, Massachusetts, in honor of his sixtieth birthday, February 17, 1936. Edited and copyrighted by Robert T. Monroe, and printed by the Waverly Press, Baltimore, Md.

EXACTLY 1000 pages of excellent, valuable, original contributions, not appearing elsewhere, have been here assembled as a birthday volume to honor Dr. Henry A. Christian, teacher at some time to each of the authors. The subject material is well diversified and touches the following fields: cardiovascular disease, renal medical disease, metabolism, pulmonary disease, blood disease, parasitology, syphilis, general therapy, dermatology, medical economics.

Perhaps the least in numbers are the contributions to gastro-enterology; those that appear are, however, excellent. Halbersleben emphasizes the importance of gray stools as a manifestation of congestive heart failure. Golden finds that some of the symptoms accompanying calcified mesenteric lymph nodes are due to mechanical irritation of the small bowel by the nodes producing spasms. Burnett offers very considerable food for prolonged thought in an article entitled "The Intestinal Rate, Normal Nutrition and Health. New Principles for the Maintenance, Restoration and Control of Health." The general idea underlying Dr. Burnett's thesis and practice is "anabolic nutrition," induced by proper ways of eating and living. One of the principal guides is an estimation of the intestinal rate or the time it takes a marked sample of food to appear and cease appearing at the anus. Success is judged critically by the consistency and configuration of the stools. Assimilation of food is the most neglected factor in nutrition. His approach to the subject appears to be rational, well considered and free from faddism. A careful reading of his paper to appreciate the results obtained by regimentation of the colon is strongly advised. W. T. Vaughan contributes an enlightening paper on the mechanism and significance of the allergic response, which stimulates new viewpoints on this vastly important subject.

The book is beautifully bound and arranged. If its publication serves to set an example in "birthday" volumes, this new phase of publication practice must be a welcome one to the medical profession.

Beaumont S. Cornell, M.D.

SECTION X—*After "Hours"*

Raoul Bensaude of Paris

By

MARTIN J. SYNNOTT
NEW YORK, NEW YORK

NO man now living has done more than Raoul Bensaude to promote the specialty of proctology and procto-enterology on the continent of Europe. For many years he has been at the head of one of the world's foremost institutions specializing in diseases of the rectum and anus. His standing in Paris as a physician and diagnostician is comparable with that held in London by J. P. Lockhart-Mummery as a surgeon. The publication of his *Treatise on Recto-Colic*

Submitted November 26, 1935.

RAOUL BENSAUDE

Endoscopy (1) was an epochal event in the history of endoscopy and digestive pathology and placed Bensaude in the front rank of contemporary procto-enterologists. This important and original work was first published in 1919 and since that time there have been several editions.

EARLY MEDICAL CAREER

Bensaude was born a citizen of Portugal at Ponta Delgada, Azores, January 27, 1866. He went to Paris in 1886, and shortly afterwards began his medical studies, receiving his Doctor's degree in 1897. During these years he was fortunate in being a pupil of such eminent teachers as Millard, Fournier, Josias, Debové Achard, Hayem, Soca, and Lion. He worked hard, was always at the head of his class, and his graduation thesis won for him the title of "Laureate" of the Faculty of the Academy of Medicine (2).

For several years before his graduation Bensaude, inspired by Achard and Debové, had made bacteriological research his major interest, and in 1898, one year after obtaining his Doctor's degree, he was head of laboratories at the Faculty of Medicine, and in 1902 head of the clinical laboratory in the department of his teacher, Hayem. The work which he did during this period and in the next seven years, alone or in collaboration with Hayem, is of the greatest importance. Three achievements are especially noteworthy: the *discovery of paratyphoid* infections (rediscovered four years later, under the same name, by a German, Schottmuller of Hamburg); his remarkable graduation thesis on *serodiagnosis by agglutination of microbes;* and the discovery of the *serodiagnosis of cholera* (1898).

Bensaude had also found time for hematological research and we owe to him the remarkable works on *hemorrhagic purpura* (1897), *its chronic forms* (1905); *the relation of purpura and tuberculosis* (1908).

With Launois, he described *symmetrical adenolipomatosis with cervical predominance* (1899); later, this was named "Launois-Bensaude's disease."

ENTRANCE INTO FIELD OF GASTRO-ENTEROLOGY

As a result of Bensaude's first work with Soca (1900), Hayem (1905), and Lion (1907) and the inspiration and encouragement received from these eminent teachers, his inclinations, however, turned gradually more and more towards diseases of the digestive tract. In 1909 he was nominated Physician of the Hospitals and ten years later he was installed as head of the department of diseases of the alimentary canal in the Hôpital Saint-Antoine, the institution of his choice and the hospital pre-eminently of specialists of the digestive tract Here he has elected to remain ever since.

From the beginning of his medical career Bensaude was especially interested in the improvement of diagnostic procedures, particularly instrumental exploration, direct or indirect. He was one of the first to employ electrically lighted endoscopes for gastric and rectal examinations and to perfect the technique of the application of such apparatus and among the first to use a jointed or adjustable esophagoscope, externally lighted. He devised numerous rectal instruments which are still in popular use. In the field of radiology we owe to him the *use of a protective screen for radiological examinations* and especially the *use of creamy barium sulfate* for roentgen examinations of the digestive tract (with Ronneaux and Terrey, 1911).

Always alert to the importance of methodical and efficient organization of his hospital service, with a view to scientific research and teaching, Bensaude surrounded himself with carefully selected assistants whom he encouraged to work along highly specialized lines for which, in his judgment, they showed special talent. Several of the best known radiologists, electrotherapeutists, internists, and surgeons in Paris owe their start to Bensaude's inspiration and advice Among these are Charrier, associate of Gosset at the Salpêtrière, to whom Bensaude refers his major surgery and whose abdomino-perineal excision for cancer of the rectum and sigmoid compares favorably with that of the world's best surgeons; Marchand the radiologist; A. Lambling the electro-therapeutist, and numerous others. These men visit his clinic frequently and are always at his command for consultation and assistance.

Bensaude is an ex-President of the Paris Gastro-Enterological Society (1930), an honorary member of the Royal Society of Medicine, London, and of the American Gastro-Enterological Association.

MEDICAL PUBLICATIONS

In addition to the works already mentioned, Bensaude has published many masterful articles These include: *multiple cancerous strictures of the gastro-intestinal canal,* which he identified with linitis (with Ockinczyc, 1906); *idiopathic dilatations of the eso-*

phagus (1908); *bilocular syphilitic stomach* (with Béclère, 1911); *radiodiagnosis of cancer of the large intestine* (with Guénaux, 1917); *radiologic study of constipation* (with Constantin, 1918); *study of severe forms of recto-colitis* (with Cain and Antoine, 1919), etc.

In the United States, Bensaude is best known for his *Treatise on Recto-Colic Endoscopy* which has already been mentioned. It is an excellent interpretation of Bensaude's numerous and patient rectoscopic investigations. Unfortunately it has never been translated into English, owing to the expense involved in the reproduction of the numerous colored endoscopic plates, but in the latest edition the sub-titles and explanations of the plates are in English. This book is an invaluable guide and atlas to all students and teachers of diseases of the lower bowel.

Bensaude's more recent publications include: *Hemorrhoids and their treatment* (with P. Oury, 1930) (3); the first three volumes of a work on *Diseases of the intestines* (4) (in collaboration with his pupils), the third volume of which is only recently off the press and the fourth of which is to appear in 1936; a report to the surgical congress of 1934 on *Strictures of the rectum* (with A. Lambling) (5); a report to the congress of Plombières on *Ulcerous recto-colitis* (with J. Rachet, 1935); a report to the International Congress of Radiologists, Zürich, 1934, on *Indications for Roentgen treatment in benign ano-rectal diseases* (with Solomon and Marchand) (6). His chief collaborators are almost all departmental heads in the hospitals of Paris.

THE HOPITAL SAINT-ANTOINE CLINIC

Through the generosity of an American friend, Mr. Lucius Littauer of Gloversville, Bensaude was able to found a consulting service of proctology at the Hôpital Saint-Antoine. The number of attendances at this clinic now exceeds 30,000 a year, the only foreign rectal clinic comparing with it in attendance being that of St. Mark's Hospital in London, where the total number is about 10,000 a year. The Hôpital Saint-Antoine clinic is cosmopolitan and, as at St. Mark's, visitors from the four corners of the globe may be met there almost daily. Bensaude has founded a real school of diagnostic and medical proctology with numerous pupils, both French and foreign.

The clinic is practical and efficient in arrangement and equipment, although quite primitive in appearance compared with the proctologic examination room at St. Mark's (14).

Bensaude's method of digital examination is slow and very thorough and while making it he dictates to the historian in considerable detail. A complete sigmoidoscopic examination is done on every new case, but the 6 inch proctoscope is used in ordinary daily work. Illumination is secured from a forehead lamp, or a large operating room reflector so placed as to direct the light over the examiner's left shoulder. Electrically lighted instruments are used only in sigmoidoscopy.

Two tables in separate screened cubicles are reserved for Bensaude's exclusive use, so that while a patient is being examined in one compartment, another is being draped and prepared in the next, thus avoiding loss of time. A third compartment is used by an assistant, and a fourth is reserved mainly for electro-therapy. The patients are examined in the knee elbow or genupectoral position (right cheek resting on table), arms around (grasping) table, and voluntary lumbar lordosis is encouraged. This position is changed to the dorsal decubitus if abdominal palpation is indicated. An individual sheet of unironed unbleached muslin is used for draping each patient. The examiners use large-fingered heavy gloves, also two-fingered ones and finger cots.

Crystallized potassium permanganate is employed to control hemorrhagic oozing after minor surgical procedures in the peri-anal region; the application of a few crystals stops the bleeding immediately. Anesthetic oils are used only for underlying painful fissures (7, 14, 8). Unhealed peri-anal wounds, post-operative chronic infections, indolent anal ulcers, or ulcerated fissures are treated with a wet dressing of acidophilus culture (Lactomose-Pansement).

Bensaude does not find pruritus ani so troublesome as it is often reported in this country. Nearly all of his cases respond to soothing lotions or powders, local hygiene, removal of pathological conditions in the anus (9, 16, 18), relief of constipation (17) and toxic colon (15, 19). A favorite lotion is "Eau d'Alibour" the formula of which is:

℞	Sulfate of copper.....	1 gram
	Sulfate of zinc.....	4 grams
	Tinct. of safron.....	1 c.c.
	Spirits of camphor.....	10 c.c.
	Aq. dist. q. s. per.....	1000 c.c.

This preparation may also be prescribed in ointment form. Peri-anal injections with anesthetic oils, alcohol, or other agents are never used, nor is it found necessary to advise radiation or undercutting procedures.

Bensaude does not associate rectal diseases with focal infection to the extent that many Americans do, because the attendance at his clinic is so large that it would not be possible to examine teeth, tonsils, sinuses, and gall tracts. He is, however, familiar with the work done by B. B. Vincent Lyon of Philadelphia and recognizes the importance of his successful treatment of many procto-enterologic conditions of toxic origin by non-surgical biliary drainage (10, 13).

When the Frei test is positive, as is often the case in rectal stricture, the patients are treated with iodine by mouth or intramuscularly, but iodine is never used locally in the rectum.

Ulcers in the rectum and ulcerative colitis are treated with Laristine (Roche) a preparation of histidine, administered intramuscularly and from the use of which Bensaude claims many spectacular results. The American preparation is known as Larostidin-Roche.

As in America, ichthyol is freely used in treating anal and rectal inflammation. Bensaude's favorite prescription is:

℞	Ichthyol	50%
	Petrolatum	25%
	Lanoline	25%

Constipation is treated with mineral oil: one-half ounce 10 minutes before breakfast and, if necessary, a similar dose before the evening meal. Should the condition persist, psyllium seed (one-half ounce softened in water) is prescribed in addition to the mineral oil, to be taken in the mid-forenoon and mid-afternoon. In very severe cases the patient is instructed

to take a warm olive oil enema (one-half pint) at bedtime.

Amebic dysentery is treated with stovarsol: one or two compressed tablets before breakfast, every other day during 15 days each month. On the intervening days the patient is instructed to take 2 or 3 teaspoonsful of the following paste:

℞ Pure bismuth subnitrate
Charcoal
Simple syrup
Glycerine ..... aa 50 grams
Ipecac powder ..... 2 grams

RADIATION THERAPY

Bensaude makes extensive and apparently successful use of radium and the Roentgen ray in his therapy of rectal diseases. In this he differs from most American proctologists, whose experience with both of these agents has been disappointing.

Cancer: Radium in massive doses is used in the treatment of cancer of the terminal colon. It is frankly admitted that the patients frequently suffer great discomfort after its application and require morphine to allay the suffering, but many cures are claimed. *The danger of post-radium bowel obstruction is overcome by performing a preliminary colostomy before application of the radium.*

Fistula-in-ano: Bensaude's outstanding achievement with the Roentgen ray is in the treatment of fistula and fissure. He claims that radiotherapy, as he applies it, has cured 50% of chronic, multiple, complicated, recurring, previously operated cases of fistula-in-ano and caused a marked improvement in 30%. It is equally valuable in the treatment of unhealed, painful, chronic fissures. The fact that his cases have uniformly been without unfortunate sequelae and have yielded such remarkable results, justifies a detailed account of his technique (6).

Careful preliminary study of the fistulous canal is made by the injection of a substance opaque to X-rays (Lipiodol, bismuth paste, etc.) and plates are taken. In cases of simple fistula with superficial canal surgical excision is advised, X-ray treatment being reserved for the complicated variety with tortuous canals, where surgery is difficult and often unsuccessful.

The patient is given a total maximum dose of 2000 r., and 200 r. each session; it is preferable to prolong the dosage and weekly sessions are now the rule. An extremely penetrating radiation is not necessary, but there should always be strong filtration (0.5 m Cu. and 2 mm Al) in order to protect the skin, because of the frequent repetition of the dose. Two or three series of treatments are given, with an interval of two months between the first and second series, and four or five months between the second and third series. Following the immediate clinical improvement that almost invariably occurs, the lesion itself usually remains unchanged until the end of the first series of treatments. However, in some cases, it was noted that the suppuration decreased and even disappeared during the first course of treatment. Most frequently the discharge ceases a few weeks after the last irradiation. If suppuration persists after two months have passed, a second course of irradiations is instituted; if necessary, a third series four months after the second. The majority of cures are obtained after one to two series of irradiations.

The technique just described has no after-effects for men; it is different with mature women, since after treatment a temporary cessation of menstruation must be expected. In these cases a tangential irradiation of the perineal region must be employed and the dosage which might injure the ovaries must be reduced to the smallest quantity.

Anal Fissures: A number of cases with anal fissures and suppuration at the posterior pole of the anus were treated with X-rays. All were old recurrent fissures in which the usual methods (electro-coagulation, diathermy, anesthetic oils, sclerosing solutions) had failed. The great advantage was the almost immediate abatement of pain, sometimes from the first session. A small dose (225 r) was used weekly and the patients were examined every week in order to determine the necessity for further treatment. The irradiation is effected through an area including the anus, coccyx and sacrum. The use of a wide field seems justified by the neuralgic symptoms which almost always accompany anal fissures, causing Bensaude to regard this lesion as a trophic disturbance. The upper hemorrhoidal plexus sympathicus, the median plexus, and the roots of the sacral plexus are thus exposed to the action of the Roentgen-rays at the same time as the fissure.

As in the treatment of fistula, there was immediate improvement after the first treatment, which is explained by Bensaude as due to the action of the X-rays on the existent infectious element.

Pruritus Ani: Bensaude's attempts to alleviate pruritus ani by means of X-ray radiation have been no more successful than those made in the United States; only temporary relief has been secured. He irradiates the region around the anus, or the anus and vulva, and the coccygeal and sacral regions, with doses of 225 r once or twice a week, up to a total dosage of 1400 r. In cases with relapse, irradiation may be repeated two to three months after the first series, but after that X-ray treatment is abandoned for fear of skin troubles. For mature women, tangential irradiation only should be used.

Hemorrhoidal Thromboses: Acute hemorrhoidal prolapse, also called hemorrhoidal strangulation, is actually a phlebitis with thrombosis of the hemorrhoidal veins. For this reason, Bensaude claims that it is specially suited for X-ray treatment and that the earlier treatment is started the quicker will be the result. The most interesting point in this treatment is that it limits the duration of inflammation to a few days, while medical treatment often calls for weeks of absolute rest. Most competent surgeons condemn operative measures in the presence of strangulation, pari-anal edema, ulceration or sloughing for fear of grave complications, or even septicemia, and death.

Bensaude irradiates through a field covering the lesion, using as a first dose 150-225 r; after this first session the patient occasionally feels a return of pain and the anus seems to be the site of an intense inflammation, but usually there is no immediate reaction. The patient is re-examined four days after the first session and, if the results seem unsatisfactory, a second treatment is given. In a number of cases a cure was obtained only after six treatments at weekly intervals. Out of 17 irradiated cases, 14 cures are re-

ported, and in three cases considerable improvement occurred.

Anal Condylomata: Bensaude believes X-ray treatment is clearly indicated in anal condylomata and claims that it is specific.

Other Conditions: Although there are frequent relapses, Bensaude considers that Roentgen therapy is beneficial in purulent rectal inflammation.

In a case of diffuse recto-perianal angioma; X-ray treatment resulted in a marked retrogression of the angiomatous tissue. Local irradiation or irradiation of the spleen in hemorrhagic rectal inflammations produced only temporary results.

Contraindications: In two cases of *inflammatory stricture of the rectum,* a purulent breaking down of the lymphatic tissue of the fossa ischio-rectalis was observed following irradiation, necessitating an extensive opening of the whole region. Subsequently there were extensive purulent lesions with deeply penetrating channels and obstinate suppuration. In *rectal polyposis* the results of X-ray treatment are often merely temporary; surgical removal is preferable because of the frequent development of carcinoma.

ELECTRO-SURGERY

Diathermy, electro-coagulation, and electro-surgery are extensively used in Bensaude's clinic. In the French machines, the conducting cords or cables wind up inside the cabinet when not in use. Both the bipolar and monopolar currents are used, together with many unique types of active electrodes. Heavy lead negative electrodes are preferred to the flexible foil commonly employed in this country. The monopolar current is used for electro-coagulation of the mucosa in *rectal prolapse* or after unsuccessful Whitehead operations, and in the destruction of small *anal papillae.* In the treatment of *hemorrhoids* accompanied by bleeding, electrotherapy (diathermy) is used only in cases where there is pain; when the bleeding hemorrhoids are not painful, sclerosing solutions (urea and quinine 5%, two to three c.c. in each quadrant) are preferred. Operative procedures are reserved for the well-defined and extensive cases in which palliative treatment of any kind is manifestly unsuited; in such cases the electric snare and bipolar current are frequently employed (3).

BISMUTH SUBNITRATE THERAPY

Since Hayem's first work on the subject forty years ago, Bensaude and his other pupils have never ceased to call attention to the many remarkable properties of subnitrate of bismuth. They have made extensive research studies on its usage in gastro-intestinal pathology, showing the modification induced by bismuth in the gastric chemistry and other related subjects. They have reported its rational use in diarrhea and dysentery and gastritis; its successful employment in the treatment of organic diseases of the stomach and intestines; in spastic enteritis and colitis, in intestinal stasis, as a vermifuge, and in numerous other pathological conditions of the stomach and intestines (11).

Very large doses, up to 60 and even 70 grams daily, are frequently given, without symptoms of intoxication from the salt.

Bensaude strongly advocates subnitrate of bismuth in the treatment of constipation. He employs it in large doses only, as it is well known that small doses increase constipation.

Its use is not restricted to organic affections, as it seems to be equally beneficial in the neuro-vegetative diseases of digestive origin.

In the treatment of gastric ulcer the following method is used. In the morning, while fasting, the stomach is washed. A suspension of 20 grams of subnitrate of bismuth in 200 c.c. of lukewarm water is then introduced through the gastric tube, the tube being then rinsed with 50 c.c. of water in order to remove every trace of bismuth. The patient is put in such a position that the bismuth will be deposited precisely at the level of the ulcer. At the end of from ten to fifteen minutes the supernatant liquid is removed through the tube, the patient remaining in the same position for about half an hour. This treatment is given at first every day, then every other day, then every three days as long as the pains continue.

Many accidents—several of them fatal—were reported following the administration of creamy mixtures of bismuth subnitrate by mouth or rectum in the radiological study and exploration of the alimentary tract. In 1909 Bensaude and Agasse-Lafont studied the pathogenesis of these cases and reported that the danger of intoxication from the administration of large doses of the salt could be eliminated by observing certain rules: (1) It should not be administered to young children, on account of the intestinal flora facilitating the production of toxic nitric acid; (2) the *heavy* subnitrate of bismuth—a crystallized chemically pure salt—should be insisted upon, instead of the *light* variety, which is a mixture without a definite chemical composition, of different acidities, oxide of bismuth, etc.; (3) in order to insure purity, only the product of a well known chemical firm should be prescribed.

EPILOGUE

When Bensaude arrived in Paris, a youth of twenty years and a citizen of Portugal, he was a stranger in a strange land, and, like the Cuban, Albarran, before him, he had to struggle against all the obstacles encountered by foreigners in every country. His personality and charm of character were such that he easily overcame this handicap and his tact and unfailing good humor soon made friends of all his competitors (2). He has preserved the proverbial gayety and good nature of his Portuguese origin and no physician in Europe is more admired and respected by all who know him. He was loved first by his teachers, then by his confrères, then by his former assistants, and finally by his devoted pupils, who find in him a delightful and inspiring instructor, friend, and guide. His teaching attracts not only French students but many doctors from foreign countries, since his fame is world-wide. He brings to his work an ever fresh ardor, an ever lively curiosity as to work done in proctology in other lands, especially the United States. He is a linguist, reads and speaks English, German, Italian, and is familiar with the medical literature of all the ordinary languages. No distinction was ever more deserved than his post-war decoration with the Legion of Honor.

Although in his seventieth year, Bensaude's activity has in no way relaxed. A highly trained and experienced internist, he now devotes himself almost entirely to diseases of the rectum and the terminal portion of

the colon. His present rank at the Hôpital Saint-Antoine is Médecin Honoraire, but the men appointed to succeed him have voluntarily stepped aside and he is still in active charge of the clinic which he founded, where he may be found hard at work four mornings each week. Between clinic hours he is at his office at 139 Boulevard Haussmann, where his private consultations are held. Vacations do not appeal to him and he is seldom away from Paris except when he is called away for consultation or to address international medical congresses in other cities of Europe. More than anything else in life he enjoys work in his clinic where, surrounded by devoted assistants, consulted by his confrères, cheered by the frequent visits of former associates, and inspired by visiting physicians from foreign lands, he labors unceasingly for the good of his fellow men and the interests of science.

His private life has always been characterized by uprightness and kindness. Of him it may indeed be said, as was written years ago of a distinguished London surgeon, that he has been:

"Bold when sure,
Cautious in danger,
Kind to the sick,
Friendly with fellow workers,
Constant in duty,
Not greedy of gain." (12)

SECTION XII—"*The Clinic*"

Amebiasis Associated with Carcinoma*

By

J. ARNOLD BARGEN, M.D.
ROCHESTER, MINNESOTA

A MARRIED woman, aged fifty-nine years, came to The Mayo Clinic on March 27, 1935. She had always been well until October, 1933, when a severe dysentery had developed three days after she had left Chicago, where she had spent several weeks at a downtown hotel. The dysentery had been associated with quantities of pus and blood, and she had passed dozens of stools every twenty-four hours. Endamoebae histolytica had been found in the stools on November 22, 1933. Fourteen grains (0.91 gm.) of emetine, which had been administered in the course of a month, had caused a cessation of the diarrhea. In January, 1934, there had been a recurrence of her trouble and at that time she had had acute protruding hemorrhoids, which had been removed. In July, 1934, Endamoebae histolytica again had been found in the stools, although they had been absent during the interim. She had had abdominal cramps. Some form of arsenic had been administered for two periods of ten days each. After this, the stools had been free of Endamoebae histolytica. She had been well until January, 1935, when loose stools again had recurred, but the outstanding symptom from then on had been severe abdominal cramps. These symptoms gradually had increased and lately they had been associated with some rumbling of gas in the abdomen.

Physical examination revealed a weak, somewhat debilitated woman, who weighed 119 pounds (54 kg.), and who was 64 inches (162 cm.) tall. There was general abdominal soreness and some tenderness. Two successive examinations of the stools in as many days revealed numerous Endamoebae histolytica. A proctoscopic examination revealed a reddened and congested mucous membrane. No discrete ulcers were apparent. Roentgenologic investigations revealed an annular defect in the middle of the transverse colon, which had all the features of carcinoma. Repeated urinalyses did not disclose any abnormality. Because of the findings of Endamoebae histolytica and because emetine had not been administered for more than a year, a total of 4 grains (0.24 gm.) of this drug was administered during each of two periods of three days. These periods were separated by an interval of one week. At the end of this time, another Roentgenologic examination of the colon did not show any change in the colonic deformity. Therefore, an obstructive resection of the transverse colon was performed on April 10, 1935. This disclosed an annular polypoid adenocarcinoma, grade 2, without involvement of the lymph nodes. Later, twelve tablets of treparsol were administered in each of two periods of four days. Recovery was uneventful and she was dismissed from the hospital on June 10, 1935.

She returned to this clinic September 9, 1935; at this time, she was feeling fine. She had regained her normal weight and did not have symptoms of intestinal dysfunction.

Master Chart for Disease of the Biliary Tract*

By

WILLIAM T. DORAN, M.D.
and
EILIF C. HANSSEN, M.D.
NEW YORK, NEW YORK

IN our Out-patient Department Gall Bladder Clinic, we have found our Master Chart indispensable. A hospital rule makes it impossible to remove hospital charts from the Record Room except with special permission. Hence, the data concerning the patient's hospital stay are lost to the Out-patient Department records unless transcribed in some way. The Master Chart has solved this problem satisfactorily, for it provides a summary of the hospital chart for use when the patient returns to the Out-patient Department

*From Gall Bladder Clinic, Fourth Surgical Division, Bellevue Hospital.
Submitted March 16, 1936.

Gall Bladder Clinic for postoperative observation and biliary drainage follow-up.

The Master Chart for disease of the biliary tract is an especially arranged filing card for use in cases of disease of the gall bladder, bile ducts and liver. The card has been in use for the past ten years on the Fourth Surgical Division of Bellevue Hospital with great success. After being filled in, the Master Charts are filed and provide an immediately available detailed summary of each case. The original Master Chart, arranged in 1926, was made more complete about three years ago. This revised card (Plates 1 and 2) has met with the requirements of our Gall Bladder Clinic to date.

DESCRIPTION OF MASTER CHART

The Master Chart is 5x8" in size, made of filing card stock and printed on both sides. Space is provided for the recording of all data routinely of interest in the work-up of cases of biliary tract disease. The card is so arranged that whenever possible unnecessary handwriting is avoided by using a checking system in the interest of time saving and legibility. More than 75 observations can be recorded on the card.

On the face of the Master Chart, space is provided for name, address, age, nationality, sex, martial state, pregnancies, date of admission and discharge. The chief complaint with duration is stated briefly and described in detail later. Information regarding past illness (especially typhoid fever) and operations is then recorded. Under Present Illness, the predominating symptom, if pain, is described as regards location (right upper quadrant, epigastrium), character (dull, aching, colic), onset (gradual or sudden), radiation (to back or shoulder), aggravation, alleviation (hypo required). Associated symptoms are then noted, namely, nausea, vomiting, belching, distension, jaundice (persistent or transient), clay colored stools, fever, chills, soreness in upper right quadrant, loss of weight.

The findings on physical examination are included as follows: admission temperature, pulse, respiration, state of nutrition, presence or absence of jaundice, abnormal findings exclusive of upper right quadrant, upper right quadrant tenderness, rigidity or mass. Operative risk is also mentioned.

On the reverse side of the Master Chart are recorded laboratory data, operative notes, post-operative course, final diagnosis and condition on discharge.

The laboratory data include the cholecystogram report, describing whether or not the gall bladder was visualized, whether the gall bladder emptied normally, whether positive or negative shadows of stones were seen. The presence or absence of bile in the urine or feces is also noted, as well as the blood count. The preoperative biliary drainage findings appear as follows: amount of concentrated bile obtained, presence of cholesterol crystals or calcium bilirubinate pigment, or bile-stained pus cells, presence of free hydrochloric acid. The blood chemistry headings are the following: blood cholesterol, icteric index, direct or indirect van den Bergh tests, blood sugar, and non-protein nitrogen determination. Space is also provided for bleeding and coagulation time and blood Wassermann.

Details pertaining to operation include the following: pre-operative diagnosis, date of operation, name of operating surgeon, name of operation, operative findings (gall bladder normal, inflamed, dilated, or contracted, calculi in gall bladder, cystic duct, common duct, hepatic duct).

The card provides further space for post-operative complications, pathological reports, reports of culture of gall bladder bile, wall, cystic duct lymph node, final diagnosis, and condition on discharge.

HOW CARD IS USED

It is our custom to fill in the front of the card (history and physical findings) at the patient's bedside, preferably, prior to operation. The back of the card (work-up data, operative findings, pathological and bacteriological reports, post-operative course, final diagnosis) is completed soon after the patient's chart reaches the Record Room. The Master Chart is then filled by number after the name of the patient has been entered in a cross index alphabetical file.

ADVANTAGES OF THE MASTER CHART

1. It provides a detailed summary of a case of biliary tract disease.

2. This record is compact, easily filed, and readily available.

3. Such a chart, if properly used, guarantees a complete record of each case. A routine history may fail to elicit answers to certain questions of special interest to those interested in biliary tract disease. The Master Chart serves as an excellent check on the completeness with which a case is worked up. At a glance, it is easily noticed that a patient failed to have a cholecystogram, biliary drainage, blood chemistry, or bile culture.

4. In hospitals not using the Unit Chart System, the Master Chart is ideal for use in the Out-patient Department in the follow-up treatment of patients operated on in the hospital.

5. The card is so arranged that a minimum of time is required to record a large amount of information.

SUMMARY

1. A summary card, called the Master Chart of biliary tract disease, is described.

2. It has been used in the Gall Bladder Clinic of the Fourth Surgical Division of Bellevue Hospital for the past 10 years with increasing usefulness.

3. The card includes information on more than 75 observations of special value to those interested in the study of the disease of biliary tract. This information is recorded by a checking system, whenever possible, in the interest of legibility and economy of time.

PLATE 2

Moniliosis of the Respiratory and Digestive Tracts

By

OSCAR BERGHAUSEN, B.A., M.D.
CINCINNATI, OHIO

FUNGI form a large heterogenous group of plants, (all lacking in cholorophyll), which not infrequently cause saprophytic and pathogenic changes in man. Probably the term *monilia* should be restricted to that species of which *Monilia candida Bonorden* is considered the type. Much confusion has arisen by classifying many organisms in the group monilia. Under certain environmental conditions many representatives assume a yeast-like appearance, but under suitable conditions true ascospores are formed, placing them definitely in the *eremascaceae.*

In man these organisms occur in the digestive tract of normal individuals. The majority are saprophytes which have found a suitable substratum for growth and multiplication, and through the enzymes and toxins secreted, may interfere with the normal functions of the organs. They may cause mild to severe lesions. They gain entrance as a rule through the respiratory tract, alimentary tract, genitalia and the skin, and may involve any organ of the body.

Most physicians are familiar with "thrush," as it involves the tongue and pharynx of children or cachetic adults, causing creamy patches usually on the tongue. The organism is now called *monilia albicans*, reproducing by blastospores but also forming filaments of short irregular units which may give rise to large, oval cells appearing as short terminal chains called conidia by some, blastospores by others. It is probable that the disease is not always caused by the same organisms only some of which liquefy gelatin. The following is a typical instance of infection in an adult:

CASE REPORTS

Case 1. Mr. E. J., aged 74; no history of previous illness; was exposed to wet inclement weather for twelve hours. Following this he developed aching pains and a cough. When seen three weeks later he had a temperature of 103, pulse of 100 and a respiration of 38, with symptoms of bronchitis marked by scattered rales over the left base. The heart sounds were irregular with a distinct systolic murmur over the base.

The man was in a good state of nutrition for his age, weighing 160 lbs. Cataractous changes were present in both eyes; the nasal passages were clear; a few poor teeth remained and the soft palate, uvula and tonsillar area were covered by a greyish membrane which did not extend over the base of the tongue. A few submaxillary lymph nodes could be palpated bilaterally. The hearing was normal. The thyroid was not enlarged. The abdomen was not involved, there being no enlargement of the spleen, liver nor kidney. He had no pain and was rational.

Smears and cultures showed the presence of *oidium albicans, endomyces albicans*—a specias of monilia. The blood count showed marked anemia, leucocytosis with marked increase in the number of lymphocytes. The red cells totaled 2,500,000, the hemoglobin 52%, the white cells numbered 35,100. The differential count showed the presence of 10% polynuclear cells, 66% lymphocytes, 3% transitionals, 1% large mononuclears, 3% myelocytes, 12% lymphoblasts, and 5% immature lymphocytes. The urine was cloudy, amber in color, specific gravity 1.024, a trace of albumin, no casts, no sugar.

The temperature continued to fluctuate between 99 and 103. There was distinct improvement locally through the use of 1% gentian violet and weak permanganate solution. However the general condition became worse, the patient dying, eleven days after admission to the hospital, from the effects of pulmonary complications following his attack of influenza, chronic myocarditis, chronic interstitial nephritis and generalized arterio-sclerosis.

The organism isolated by Alfred O'Neil showed pearly white colonies on solid media; developed acid but no gas with dextrose agar; produced neither acid nor gas in mannite, saccharose and lactose agar; did not liquefy gelatin; produced no lead sulfide in liquid media containing lead acetate and formed hyphae in broth containing carrot thus differentiating it from ordinary yeast cells or saccharomyces.

An instance of mycotic infection occurring late in the course of an attack of influenza pneumonia followed by empyema is seen in the following clinical history. Undoubtedly the organism was originally a harmless invader, but later found the proper soil and environment for rapid growth. The lung tissue subsequently obtained at autopsy was examined microscopically and was found to resemble a typical tuberculous lesion; subsequent animal inoculation was negative for tuberculous infection however.

Case 2. Dentist, aged 37, admitted to hospital on November 14, 1933, with diagnosis of acute influenzal bronchitis, involving the left upper and right lower lungs chiefly. The temperature varied between 100 and 102.6, pulse 124. The urine showed one plus albumin, no casts; the blood count was 3,860,000 red blood cells, the leucocytes numbered 11,100 of which 86% were polynuclears. On November 23, 1933, the leucocytes numbered 37,650 of which 89% were polynuclears. Pneumococcus, type IV, was isolated from the sputum. The first X-ray examination of the chest made on November 22, 1933, showed the entire right side to be markedly dense especially marked in the lower two-thirds. The heart was displaced to the left. On the left side was peribronchial thickening, otherwise the left side was negative. An exudate probably purulent in nature was suggested on the right side. A preliminary drainage tube was inserted and on December 31, 1933, rib resection for right sided empyema was performed. The patient improved and from January 17th to 23rd the temperature was within normal limits. On January 25th the condition again became worse and the patient died on February 10, 1934.

The post mortem examination revealed:

1. Lobar pneumonia in the stage of gray hepatization involving the right upper and middle lobes with early abscess formation in the former.

2. *Localized necrosis of a segment of the ileum one and one-half feet above the ileocecal valve with associated*

Submitted February 13, 1936.

fibrino-purulent peritonitis producing low grade intestinal obstruction.

3. *Acute diverticulitis of Meckel's diverticulum.*
4. Right fibrino-purulent uretero-pyelitis (right), less marked on the left.
5. Thrombo-phlebitis of right innominate vein.
6. Toxic changes in viscera.
7. Pulmonary congestion and edema with possible hypostatic infiltrate in the right lower lobe.
8. Cardiac dilatation.
9. Right chronic obliterative pleuritis (incomplete).
10. Thoracotomy wound.
11. Edema of skin and soft tissues, elbows and ankles.

The microscopic examination of the lung tissue showed alveolar exudation with typical tubercle formation and areas of necrosis with giant cell formation.

The pneumococcus type IV was isolated by Alfred O'Neil from the sputum during November, 1933. In February, 1934, repeated daily examinations of the sputum failed to reveal the presence of tubercle bacilli, but did repeatedly reveal the presence of yeast-like organisms. Possible extraneous sources of this organism were carefully ruled out; cultures were made on Sabourand's and ordinary media. Pure cultures developed acid but no gas in dextrose and saccharose agar. Hyphae developed in simple broth and broth containing carrot. Inoculations into the nasal mucous membranes of a guinea pig and subcutaneous inoculations of a guinea pig gave negative results. The organism was classified as monilia albicans and was isolated from the sputum, the lung at autopsy and the pus obtained from the ureter at autopsy. Lung tissue containing hyphae obtained at autopsy and treated with 3% sulphuric acid, was inoculated into two guinea pigs. After five months one animal died but showed no evidence of tuberculosis or other bacterial infection; the other animal remained perfectly normal.

Torula is a name incorrectly used as a synonym for moniliae. Dodge (1) classifies torula as belonging to the *cryptococcus*. He mentions two groups, the one isolated from tumors and at one time considered a cause of cancer; the other group includes species such as *cryptococcus histolyticus*, which may infect the respiratory tract of man and lead to chronic meningitis and eventual death. In the differential diagnosis of atypical epidemic encephalitis, cerebral neoplasm or tuberculous meningitis, the examination of the spinal fluid for torula organisms should be borne in mind. Clinical characteristics are gradual onset with headache and stiffness of the neck, disturbances in sleep, amblyopia and diplopia developing later, associated with symptoms on the part of the respiratory tract and enlargement of the lymph glands. Sawers and Thompson (2) describe such a case of chronic meningitis due to torula as having followed the development of a granuloma that developed from a razor cut. These authors also mention a case of typical chronic meningitis as reported by Johns and Attaway, in which trauma over the scapula was followed by a deep mycotic infection which had healed many months before the onset of meningitis.

In the following abstract of a clinical history published elsewhere (3) the writer mentions a torula infection arising in the tongue, eventually leading to death by inanition after a course of eleven months.

Case 3. Man, aged 28, a laborer in a steel plant, suffered an injury to the anterior part of the tongue June 20, 1926, when a piece of hot steel flew into his mouth. When I first saw him on January 11, 1927, he had become emaciated, complained of weakness and pain on eating from the infection of the tongue. His temperature was 100 and the pulse rapid. Stereoscopic X-ray pictures of the chest showed bilateral infiltration not typical of tuberculosis. Cultures from the tongue showed the presence of torula histolytica. The blood count showed 4,900,000 red cells, 80% hemoglobin, 3,850 white cells including 54.5 per cent polynuclears, 30.5 per cent small and 5 per cent large lymphocytes, 1 per cent mast cells, 3.5 per cent eosinophiles and 5.5 per cent transitionals.

The patient improved somewhat after the injection of two doses of 0.6 gm. Neo-salvarsan and 2 grain doses of quinine sulfate given three times daily. A third intravenous injection of 0.3 gm. Neo-salvarsan made him worse and he subsequently died of inanition on May 17, 1927. Quinine sulfate and sodium iodine given internally over a prolonged period seemed to be of no benefit. An autopsy was not permitted.

ABSTRACTS

CLINICAL MEDICINE

REID, MONT R., M.D., POER, D. HENRY, M.D., AND MERRELL, PAUL, M.D.

A Statistical Study of 2,921 Cases of Appendicitis. J. A. M. A., Vol. 106, pp. 665-6 69, Feb. 29, 1936.

From a series of 2,921 cases admitted to Cincinnati General Hospital from January 1, 1915, to January 1, 1934, the following has been determined:

Appendicitis is a disease of adolescent and young adult life, and is more common in the male than in the female. The time elapsing between the onset of the symptoms and the admission to the hospital averaged 3.8 days and was found to be too long for proper surgical treatment. The symptomatology in these cases is as follows:

1. Abdominal pain located in the epigastrium or around the umbilicus.
2. Localization of the pain over McBurney's point.
3. Tenderness on palpation in the right lower quadrant.
4. Nausea and vomiting.
5. Muscle spasm and rigidity usually, but not always present.

The temperature in simple acute cases was rarely over 100 degrees F., but in cases of gangrenous appendicitis and peritonitis it averaged between 102 degrees and 104 degrees F. The temperature in children with simple acute cases sometimes went as high as 103 degrees Fahrenheit. The leucocyte count varied with the severity of the infection and the presence or absence of complications.

Approximately 60 per cent of the acute cases were admitted during the first attack, and approximately 40 per cent of all cases were admitted after rupture of the appendix. The use of purgatives was found to increase the incidence of perforation and to lessen the patient's chances for recovery. Over 98 per cent of the deaths from appendi-

citis were due to the complications accompanying perforation.

The mortality rate in acute unruptured appendicitis was 0.86 per cent; with abscess formation, 11.4 per cent; with peritonitis, 33.9 per cent.

The conclusion was reached that the time elapsing between the onset and the treatment was too long; that the death rate for complicated cases when treated by immediate surgery, is too high. It is therefore believed that the Ochsner treatment in complicated cases is superior.

POTTER, M. G., M.D.

Observation of the Gall Bladder and Bile During Pregnancy at Term. J. A. M. A., Vol. 106, pp. 1070, March 28, 1936.

The fact that many pregnant women complain of abdominal distress and pain in the right upper quadrant prompted this investigation. In 390 cesarean sections the gall bladder was inspected, palpated and aspirated. Upon some of the cases a bacteriologic and chemical analysis of the bile was made.

The following results were obtained:

1. 60 per cent of cases had cholesterol concentrations between 100 and 400 mg. per one hundred c.c.

2. 60 per cent had bile salt concentrations between 300 and 400 mg. per one hundred c.c.

3. 62 per cent had a bile salt: cholesterol ration between 1:1 and 3:1. In 7 per cent the ration was reversed (1:2, 1:3).

4. The greater the concentration of cholesterol, the greater the number and more constant was the presence of calcium, bilirubin and cholesterol crystals.

5. There was no relationship between the bile salt: cholesterol ratio and the constancy of the crystals found.

6. Only 26 per cent showed no evidence of cholesterol or calcium bilirubin crystals.

7. The five cases in which positive cultures were obtained showed a concentration under 300 mg. per cent. Of these cases four showed cholesterol or calcium bilirubin crystals.

8. In 20 cases the blood-bile cholesterol ratio was 1:1 in 8 cases; 1:2 in 8 cases; 1:3 in 1 case; 1:4 in 2 cases; 1:5 in 1 case.

The conclusions were reached that 75 per cent of normal gall bladders are distended at term. An adequate fat intake would be advisable to prevent gall bladder distress. Bile stasis in the gall bladders of pregnant women is common. Bacterial invasion is rare. Metabolic dysfunction associated with functional motor disturbance and stasis rather than infection or mechanical pressure seems to be the forerunner of biliary disease in women. Hypercholesterolemia exists at term. Postoperative nausea and vomiting appeared to be reduced by release of pressure within the gall bladder. There was no definite ratio between the blood-bile cholesterol concentrations demonstrated.

KRAEMER, MANFRIED, M.D., AND ASHER, MAURICE, M.D.

The Association of Erythremia and Duodenal Ulcer. Am. Jour. Med. Sci., p. 234, Feb., 1936.

The theory of Morris, Schiff and Foulger that erythremia was caused either by excessive secretion of a blood forming hormone by the stomach which they named "Addisin" or by susceptibility of the bone marrow to stimulation by addisin. It is noted that a year later they concluded this hemopoietic factor secreted in the normal stomach was identical with the "intrinsic factor" of Castle.

Morris et al treated a case of erythremia associated with a duodenal ulcer by lavage of the stomach 3 to 4 times weekly. On this treatment the patient's blood count fell from 10 to 5.3 millions —a few months later, without lavage, it rose again to 10.2 millions. Boyd concluded that polycythemia bore a causal relationship to duodenal ulcer and Wilbur and Ochsner studied the cases of erythremia at the Mayo Clinic and found 8% in 143 case records compared with 2% in 200 control cases of hypertension.

The writers report two cases illustrating the association of polycythemia with duodenal ulcer, one of which quickly passed from observation while the other patient co-operated and was given bi-weekly gastric lavage for three months. He was given a bland diet and alkalies. He was relieved of his ulcer symptoms but not of his polycythemia.

The Authors write that it is possible they did not perform gastric lavage frequently enough as Oerting and Briggs lavaged their patients four to six times daily and thus produced a reduction in red blood cells. The Authors make a rather startling and radical suggestion that "should a patient with erythremia and duodenal ulcer associated show a marked reduction in erythrocyte count after gastric lavage, gastrectomy might afford permanent cure of both afflictions."

Allen Jones, Buffalo, N. Y.

REICHLE, HERBERT S.

Primary Tuberculous Infection of the Intestine. Arch. of Pathol., Vol. 21:1, Jan., 1936.

A report of an undoubted case of primary tuberculous infection of the intestine of probable bovine type of origin is given, together with a brief review of the controversy started by von Behring in 1903 when he stated that a large percentage of all cases of tuberculosis originated in childhood by infection through the intestinal tract. Although now generally agreed that the bovine tubercle bacillus is virulent for man and that an ingestion form of primary tuberculous infection exists, still its exact percentage of occurrence is a matter of dispute.

The Author concludes from a study of the literature that infection with the bovine variety of the tubercle bacillus is unusual outside of England, Scotland and Wales, except when the infected person has used an infected dairy product. Infections of this sort in the United States and Canada are rare because of the general use of Pasteurized or boiled milk, and when found are usually traced to cows infected with tuberculosis. He quotes Wilson as stating in 1932 that 5.2 per cent of all deaths caused by tuberculosis in England and Wales were due to the bovine organism. This is because raw milk is generally used in the British Isles and a study by the Scotch Board of Health, for instance, demonstrated the presence of tubercle bacilli in 20 per cent of the milk tests.

BUTT, HUGH R.

Myasthenia Gravis: A Study of Postmortem Observations, Including the Demonstration of Gram-Positive Bacteria (Streptococci) in and Between the Muscle Fibers. Arch. of Pathol., 21:1, Jan., 1936.

The Author reports the study of seven cases of myasthenia gravis in which muscle tissue taken immediately after death from many locations in the body showed many gram-positive diplococci, which were taken to be streptococci, within and between the muscle fibers in sections stained for microorganisms. An equal number of control cases showed no microorganisms in the muscle fibers when studied in a similar manner.

The apparent association of preceding acute infections with the onset of myasthenia gravis is commented upon, and the suggestion is made that the underlying cause of the disease may be a type of infection which becomes localized in the muscles and that these bacteria may be the origin of the toxin which produces its characteristic fatigability.

N. W. Jones, Portland, Ore.

CAPRIO, FRANK S.

An Outbreak of Botulism in New Jersey. J. A. M. A., Vol. 106, pp. 687-689, Feb. 29, 1936.

Botulism is a comparatively rare disease, especially on the Atlantic coast, but it is rarely possible that some cases have been confused with encephalitis, acute poliomyelitis, toxic ophthalmoplegia and various types of food poisoning.

The outbreak described here occurred in March, 1935. A family of five be-

came ill suddenly, after eating a jar of home preserved peppers. The diagnosis was made early because of the typical symptomatology and history. Two members died before the botulism antitoxin was available and the other death occurred after the administration of the antitoxin.

The incubation period in these cases varied from two to sixty-nine hours after the ingestion of the toxin. The symptoms were blurred vision, diplopia, blepharoptosis, photophobia, lassitude, weakness, obstinate constipation, offensive breath, disphagia, inability to articulate, drowsiness, normal or subnormal temperature, vomiting with eructation of gas, and mental awareness.

The laboratory was unable to culture the bacillus botulinus in any of the cases.

Death in all three cases was due to respiratory failure.

Necropsy of the three cases revealed: 1. Acute toxic poisoning; 2. chronic passive congestion of all organs; 3. hemorrhage into the stomach.

The impression of the pathologist was atoxic neuronophagia. The poison seemed to come from the toxin of the bacillus of botulism.

Treatment was both specific, consisting of the administration of botulinus antitoxin A and B, and symptomatic.

Francis D. Murphy, Milwaukee.

EXPERIMENTAL PHYSIOLOGY

EKLAND, CARL M., AND REIMANN, HOBART A.

The Etiology of Amyloid Disease, with a Note on Experimental Renal Amyloidosis. Arch. of Pathol., 21:1, Jan., 1936.

The Authors discuss briefly the various theories of causation of amyloidosis of the secondary type; the type characterized by large deposits of typical amyloid substance in the liver, spleen and kidney which follows in the course of chronic diseases.

Experimentally in five rabbits they produced extensive amyloidosis of the kidneys by the intramuscular injection of 5 c.c. of a 10 per cent solution of sodium caseinate three times a week until shortly before death. Two animals died in eight months, one in eleven months, one in thirteen months, and the fifth in seventeen months after the first injection. Evidence of illness was usually noted two or three months before death. The latter occurred with the signs and symptoms of nephrosis or nephritis and uremia. Four had minimal changes in the liver and spleen while the fifth, which lived the longest, had extensive amyloid changes in these organs as well as in the kidney.

Hyperglobinemia developed in each rabbit soon after the beginning of the experiment and continued until death. Total protein content of the blood was increased early but sank below normal levels after renal damage and uremia appeared. The experiments support the view that chronic hyperglobinemia is an important factor in the etiology of amyloidosis of the secondary type.

KELLER, ALLEN D., AND D'AMOUR, MARIE C.

1. *Ulceration in the Digestive Tract of the Dog Following Intracranial Procedures; Preliminary Study.*
2. *Protection by Peripheral Nerve Section of the Gastrointestinal Tract from Ulceration Following Hypothalmic Lesions, with Preliminary Observations on Ulceration in the Gastrointestinal Tract of the Dog Following Vagotomy.*
3. *Ulceration in the Digestive Tract of the Dog Following Hypophysectomy. Arch. of Pathol., 21:2, pp. 129, 165, 186, Feb., 1936.*

In a series of studies on ulceration of the digestive tract in dogs, following experimental lesions of the brain stem, Keller and Keller and D'Amour found hemorrhagic states in the mucosa of the stomach in a high percentage in one series and characteristic crater formation in the mucosa of the body of the stomach in another series. In no instance were gross or histologic evidences of the latter lesions associated with the former. The hemorrhagic states occurred spontaneously after complete destruction of the anterior portion of the hypothalamus. Craters were never found unless part of the anterior portion of the hypothalamus was intact. This suggested, in the author's opinion, that the hemorrhagic states were precipitated by the activation of the sympathetic outflow (posterior portion of the hypothalamus) and the craters by activation of the parasympathetic outflow (anterior portion of the hypothalamus).

Acute and chronic ulceration in the stomach followed vagotomy alone only when the dogs were subjected to yard conditions during the winter months and were not found in dogs protected by cage regimen. In a series of dogs in which bilatetal vagotomy was performed before a chiasmal lesion was produced, hemorrhagic states were found but no ulcers occurred. In another series the abdominal portions of the sympathetic chains were removed prior to the placing of a chiasmal lesion and in this group typical gastric and duodenal ulcers were formed whereas no hemorrhagic states were to be found.

Hemorrhagic states and gastric and duodenal ulcers were found in a percentage of cases after hypophysectomy, and were identical with those which occurred after chiasmal lesions. The authors present evidence which indicates that the ulceration was precipitated not because of the lack of hypophyseal secretions but because of a neighboring neural derangement, possibly intraventricular stimulation, as a result of opening the third ventricle during the operation. The studies are detailed: many protocols of experiments with photographs and microphotographs of the anatomical material are given.

ROENTGENOLOGY

SCOTT, WENDELL G., M.D., AND MOORE, SHERWOOD, M.D.

A Method of Roentgen Diagnosis of Non-Opaque Foreign Bodies in the Esophagus. J. A. M. A., Vol. 106, pp. 906-908, March 14, 1936.

The most frequent non-opaque or radiolucent object to become lodged in the esophagus is a piece of unossified bone from a fowl or fish. The next most frequent object is a button or a bolus of food. These objects usually may be found lodged at the level of the suprasternal notch, but also at the introitus, at the level of the left bronchus, and at the diaphragm.

The initial symptom is usually a gagging or choking, followed by a feeling of apprehension, dysphagia, adynophagia, exaggeration of the movements of swallowing, and drooling.

The roentgenographic procedure is to take anteroposterior and lateral views first. If this does not visualize anything, the patient is placed in front of the fluoroscope and given a thick suspension of barium sulfate in water, and carefully observed to determine whether there is a deviation or division of the stream or a filling defect. After this, it is noted whether any of the barium is clinging to the foreign body.

Next, a film of the entire esophagus is made. This is done by having the patient drink a very thin, watery solution of barium through a glass tube in short, quick swallows. Exposures are made in both the anteroposterior and the right anterior oblique positions. The barium coats the esophageal walls and produces a constant filling defect. It also coats the foreign body, revealing it as a collection of opaque material.

Francis D. Murphy, Milwaukee.

ABDOMINAL SURGERY

LEWISOHN, RICHARD, M.D.

Recent Advances in the Surgical Treatment of Chronic Duodenal Ulcers. J. A. M. A., Vol. 106, No. 9, pp. 684-687, Feb. 29, 1936.

The surgical treatment of gastro-duodenal ulcers is at present the subject of much controversy. In the past fifty years many procedures have been ad-

It Happened — in Kansas City

A miniature working model of an Irradiated Pet Milk plant was displayed at the annual meeting of the American Medical Association in Kansas City.

Several thousand physicians saw there, with much interest, the actual operation by which Pet Milk is produced. The concentration to double richness, the irradiation, homogenization and sterilization were all definitely demonstrated.

These processes produce in Pet Milk the following qualities of definite interest to the gastro-enterologist.

1 Uniform double richness, which facilitates the inclusion of more milk in the diet.

2 Freedom from all bacterial life — a safeguard against infection or intestinal irritation from this source.

3 A more ready digestibility because of the formation of small, soft, non-irritating curds.

4 Hypo-allergic effect on the patient sensitive to milk.

5 Richness in vitamin D created by irradiation with ultra-violet rays.

6 Inexpensive, costing less than other forms of milk, often only half as much as bottled milk.

PET MILK COMPANY, 1446f Arcade Building, St. Louis, Missouri

vocated from gastro-enterostomy, local resection, sleeve resection, to partial or subtotal gastrectomy.

The Author believes that partial or subtotal gastrectomy is preferable to gastro-enterostomy. He believes that the occurrence of gastrojejunal or jejunal ulceration and the persistence of symptoms is too high in gastro-enterostomy. The patient frequently is not improved, the hyperacidity persists, and the pylorospasm frequently remains after the operation. He believes the percentage of occurrence of gastrojejunal ulcers following gastro-enterostomy is between 34 and 50 per cent. The mortality rate for re-operation in cases of gastrojejunal ulcer is about 20 per cent, while the mortality for subtotal gastric resection varies from 1.5 to 3.1 per cent in the hands of well trained surgeons. This surgical procedure shows the frequence of gastrojejunal ulcer to be about 7 per cent.

The Author says that in his follow-up clinic complete restoration to health is the rule, and complaints of gastric distress the exception.

CULLEN, THOMAS S., M.D.

Intestinal Obstruction Due to a Hole in the Mesentery of the Ascending Colon. J. A. M. A., Vol. 106, No. 11, pp. 895-898, March 14, 1936.

Intestinal obstruction due to abnormal openings in the mesentery is probably the rarest of all etiological factors. Cases of this malady have been reported by Edwards, Brown, Cutler, Elston, McWhorter, Juad and Hamaker.

According to Edwards, there were only two cases of obstruction of the large bowel ever reported. This present case is one in which there was an opening in the mesentery of the ascending colon.

The history of this case in brief is as follows:

A doctor's son, 11 years of age, who had always been in excellent health except for attacks of abdominal pain of short duration and relieved by vomiting, for the past two or three years. He had also complained of pain in the side of the abdomen after running, and of pains in the legs after any strenuous exercise. Three months previously, he complained of severe abdominal pain, lasting for five minutes and occurring after playing football.

In the past three months he had appeared more tired than usual, turned pale on several occasions and almost fainted.

The day before this attack he had felt the same as usual. That night it was noticed that he was snoring in an unusual manner. He awoke at 2:30 the next morning with slight abdominal pain, which gradually became worse, until at 6:30 A. M., when his father saw him, the pains were acute paroxysmal and generalized. Examination revealed no localized tenderness and no muscular rigidity. Some nausea was present, but attempts to vomit were unsuccessful. Operation was decided upon immediately.

A grid-iron incision was first made, and bluish-black bowel was seen. A *mid-line incision was made immediately* and a hole about two centimeters in diameter was found in the mesentery of the ascending colon. Through this a loop of large bowel had passed and become gangrenous and distended.

Corrective surgical measures were instituted and recovery was uneventful except for severe abdominal distention and a pharyngitis and bronchitis of moderate severity.

Francis D. Murphy, Milwaukee.

Creamalin

The Specially Prepared
Colloidal Cream of Aluminum Hydroxide
. . . . for the ACID FACTOR in Peptic Ulcer

Granting other primary factors, it is now acknowledged that the most important factor and immediate cause of Peptic Ulcer is the acid digestion of the affected tissue. Desirable ant-acid therapy is, therefore, indicated.

Creamalin presents a most desirable ant-acid therapy. It possesses a much higher combining power than the soluble alkalies, (one volume combining with fourteen volumes of one-tenth normal hydrochloric acid in one hour by physical fixation) without the attendant dangers of alkalosis

Creamalin provides prompt relief of pain, nausea, and pylorospasm. (Usually within twenty-four hours). Creamalin therefore should be employed in all cases of Peptic Ulcer, especially those that have been refractory to previous therapies.

Write for reprints reporting on its use by the continuous drip method. Material for clinical evaluation available on request.

CLEVELAND CHEMICAL ASSOCIATES
Cleveland, Ohio

The Summer-Time Use of
Mead's Oleum Percomorphum

During the hot weather, when fat tolerance is lowest, many physicians have found it a successful practice to transfer cod liver oil patients to Mead's Oleum Percomorphum.

Due to its negligible oil content and its small dosage, this product does not upset the digestion, so that even the most squeamish patient can "stomach" it without protest.

There are at least two facts that strongly indicate the reasonableness of the above suggestion: (1) In prematures, to whom cod liver oil cannot be given in sufficient dosage without serious digestive upset, Mead's Oleum Percomorphum is the anti-ricketic agent of choice. (2) In Florida, Arizona and New Mexico, where an unusually high percentage of sunshine prevails at all seasons, Mead's Oleum Percomorphum continues increasingly in demand, as physicians realize that sunshine alone does not always prevent or cure rickets.

Mead Johnson & Company, Evansville, Indiana, invite you to send for samples of Mead's Oleum Percomorphum for clinical use during the summer months to replace cod liver oil. Adv.

Have you thought of doing without barbiturates in your practice?

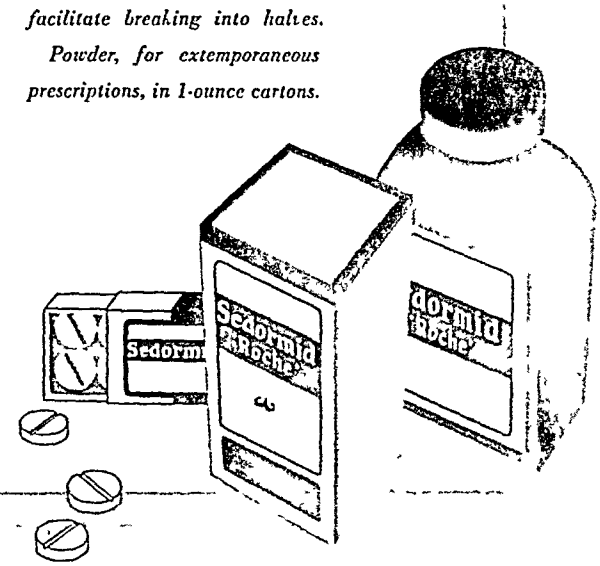
Many physicians have found that Sedormid completely and safely replaces the barbiturates. Sedormid is not a barbiturate, and yet it is a dependable, gently-acting sedative and hypnotic. It doesn't have the sledge-hammer, sleep-enforcing effect of the barbiturates. Instead, it allows sleep to come in a more natural way, by merely overcoming tension and apprehensiveness,—in a word, by promptly removing the barriers to sleep.

*SEDORMID 'Roche'

As a day-time sedative 1 to 2 grains three times a day. Internists find it incomparable for quieting the super-charged nervous system in cases of hyperthyroidism. Neuropsychiatrists prefer it for systematic sedation in anxiety states and other neurotic manifestations. The thin undernourished patient with "nervous" indigestion or with gastro-intestinal hypermotility, the woman in menopause with vasomotor instability, the menstruating woman with nervous irritability—all these, and others that fall in the same category, receive gratifying benefit from small day-time doses of Sedormid. Bromides, in ordinary doses, are too weak; barbiturates are too strong; Sedormid, neither a bromide nor a barbiturate, meets the indication precisely.

As a hypnotic 4 or 5 grains about 20 minutes before sleep is desired. Indicated in all cases of insomnia, regardless of the cause.

Packages. *Tablets, 4 grains each, in boxes of 10 and bottles of 100.*



The tablets are scored across the center to facilitate breaking into halves.

Powder, for extemporaneous prescriptions, in 1-ounce cartons.

*(allyl-isopropyl-acetyl-carbamide)

New report shows

BRAN HELPS MAINTAIN IRON SUPPLY

of the human body

THE November, 1935, issue of the *Journal of the American Dietetic Association* reports a comparative study of bran and egg-yolk, a known rich source of iron.

The subjects were healthy young women. The conclusions developed by the experiment were *"that the iron of egg-yolk and of bran can be used with equal efficiency for the maintenance of iron equilibrium in the human adult."*

This study continues a series of researches, conducted over a period of five years, in which new contributions to our information on bran have been made. Some of these tests have confirmed the value of bran as a safe laxative food for normal people. Others have demonstrated that it does not lose its effectiveness with continued use.

Further independent tests on men have indicated that the "bulk" in bran is often more effective than that found in fruits and vegetables.

Laboratory studies have shown that Kellogg's ALL-BRAN supplies "bulk," which absorbs moisture and gently cleanses the intestinal tract. This delicious cereal corrects constipation due to insufficient "bulk."

ALL-BRAN may be served as a cereal, with milk or cream, or cooked into muffins, breads, etc. Sold by all grocers. Made by Kellogg in Battle Creek.

The natural food

THAT CORRECTS CONSTIPATION

due to insufficient "bulk"

BLAHD, M. E.

"Surgical Indications for Peptic Ulcer and Its Surgical Management." S. G. O., 62:203-212, Feb., 1936.

To the usual positive indications for surgical treatment of peptic ulcers (perforation, pyloric obstruction, and, occasionally, severe and uncontrollable hemorrhage) the author adds the deep penetrating type of ulcer. This latter type, he believes, is impossible to cure medically and when recognized by X-ray examination (which is usually not difficult) should be subjected to operation. The type of operation preferred is subtotal gastrectomy and a rather convincing proof of its superiority is offered. Analysis of statistics is presented showing a larger percentage of immediate cures, there is practically no secondary mortality, the difference in primary mortality is more than compensated by mortality of secondary operations, jejunal ulcer is practically never encountered, and the patient is immeasurably more comfortable in all ways including the liberality of his diet.

A detailed illustrated description of the operation is included in the article.

J. Duffy Hancock, Louisville.

BARTLETT, WILLARD, JR., M.D., AND BARTLETT, ROBERT W., M.D.

Perforation of the Gall Bladder with Massive Intraperitoneal Hemorrhage. J. A. M. A., Vol. 106, pp. 615, 616, Feb. 22, 1936.

Perforation of the gall bladder is in itself a comparatively rare lesion, but when accompanied by massive hemorrhage it is an event of extreme rarity. Only two cases have been reported in the literature since 1900.

This is the report of a case of a 65 year old woman who entered the hospital with the complaints of abdominal pain, distention of the abdomen and constipation.

In the past year the patient has had two acute attacks of epigastric pain radiating to the interscapular area and relieved by vomiting. Two days before admission, the patient had a similar attack not relieved by vomiting and followed by progressive distention, not relieved by enemata. The patient had seven attacks of vomiting in the three days, and one bowel movement shortly after the onset of the attack; there was no passage of the stool or flatus after that.

Physical examination of the patient upon entering the hospital revealed an obese, dehydrated woman with severe abdominal distress. The abdomen was distended and presented generalized tenderness, no rigidity, but dullness in the flanks. Pelvic and rectal examinations were negative. Temperature—104.4; pulse—102; respiration—40; B. P.—165/20; hemoglobin—62 per cent; R. B. C.—3,396,000; W. B. C.—20,000.

CONTROL

The strict control which is exercised in the manufacture of Petrolagar is one of the chief reasons for its efficiency. Every step in the process of making Petrolagar, from tests of raw materials on through each phase in its production, literally comes under the exacting scrutiny of the microscope. Because of this control Petrolagar can always be relied upon for its uniform consistency and action.

Petrolagar is a palatable emulsion of pure liquid petrolatum, (65% by volume) and number One Silver White Kobe Agar-agar, accepted by the Council on Pharmacy and Chemistry of The American Medical Association for the treatment of constipation

Petrolagar Laboratories, Inc., 8134 McCormick Blvd., Chicago, Ill.

The Schilling count showed segmented forms 78 per cent, stabs 10 per cent, lymphocytes, 11 per cent, and monocytes, 1 per cent.

X-ray of the abdomen revealed distention of the large intestine and cecum.

Operation revealed a tear on the under surface of the gall bladder from which venous blood was welling. The peritoneal cavity was filled with about two liters of fluid blood.

The patient progressed for a short time, but then took a turn for the worse, and rapidly succumbed to a broncho pneumonia.

Autopsy revealed a rupture of a gall bladder, the seat of a chronic cholesystitis with cholelithiasis.

Francis D. Murphy, Milwaukee.

HUEPER, W. C.

Spontaneous Arteriosclerosis in Rats. Arch. of Path., 20:5, 708, Nov., 1935.

In general it is agreed that experimental arteriosclerosis has been produced only in rabbits and to a less extent in guinea pigs, that such lesions have not been produced in other laboratory animals. Spontaneous arteriosclerosis in rats is supposed to be of infrequent occurrence. Hueper reports the finding of arteriosclerotic lesions in the branches of the pulmonary artery in 12 rats out of a series of 75. In the arteries of no other organs were such changes observed. These rats were adult and their death had been produced experimentally in a manner which could not have caused degenerative arterial changes. The lesions were found mostly in the large and médium sized branches near the points of bifurcation. Multiple plaques were usually present. The majority of lesions consisted of cone shaped calcified foci, covered by endothelium, projecting into the lumen. They were located in the subendothelial tissues and frequently extended into the media which showed local hyaline degeneration. There were at times indistinctly outlined streak like formations which involved only the media, and, again, small hyalinized areas containing calcifications were observed involving only the media. The intima covering the foci was usually thickened and the seat of cellular infiltration. There existed more or less hypertrophy of the media in many of the smaller arterial branches. Complete obliteration of the lumen was observed once. The deposition of lipoids in the walls of these vessels was not studied.

HUET, P.

Prolapse of the Lowered Colon in a Case of Resected Rectum. Operative Cure by Hystero-Hyero-Pexie (Utero-Sacral Fixation). (Prolapsus du côlon abaissé chez une amputée du rectum. Cure opératoire par hystéro-hyéro-pexie. Fixation utéro-sacrée). J. de Chir., Tome 46, No. 6, p. 363-366, 1 Fig., Sept., 1935.

Having a case of his own to deal with, the author describes a technique capable of yielding good results where prolapse of the lowered loop of colon occurs following amputation of the rectum for cancer. Several fruitless operations having been tried previously and the classic method of the obliteration of the pouch of Douglas has been judged impracticable. The author conceived the idea, for this case, of utilizing the uterus and broad ligaments for filling in the pelvic excavation. For this purpose he fixes the fundus of the uterus to the promontory after transverse incision of the peritoneum, in front of the bony prominence after separation of the fatty pelvic tissue and denudation of the fibro-periosteal layer which cover the anterior surface of the sacrum. The posterior surface of the fundus is fixed to the fibrous presacral tissue by three bridges of linen thread. The pouch of Douglas is obliterated by the fixation of the round ligaments to the superior inlet. On the right, the whip stitch is continued and closes the breech completely. On the left the whip stitch is stopped at the point where it encounters the pelvic colon, thus aiding the latter in its easy descent into the pelvis. Four or five separated sutures drawn together fix the pelvic colon to the broad ligament, closing all communications between the large cavity and the pouch of Douglas, henceforth excluded. The superior lip of the incision of the presacral peritoneum is sutured to the anterior surface of the fundus uteri thus peritonealizing the suture of the utero-sacral fixation.

Cure has been maintained since two and one-half years.

The test of time attributes to this operation a curative value. It is applicable to the non-hysterectomized woman when all possibility of pregnancy has disappeared; it may not be practiced until after the menopause; if the uterus conserves dimensions allowing it to be brought without rough tearing in contact with the sacrum. It is an exceptional procedure, but on occasion, a definite cure.

HUNT, V. C., AND BUDD, J. W.

Transduodenal Resection of the Ampula of Vater for Carcinoma of the Distal End of the Common Duct. S. G. O., Vol. 61, No. 5, pp. 651-661, Nov., 1935.

The incidence of malignant disease of the periampullary region can not be stated with very great accuracy since such conditions in that situation have received but little attention until recently. Certainly the number of cases attached surgically is a very low estimate of their incidence. One-third of all new growths of the bile ducts originate in the lower end of the common duct and practically always they are carcinomas.

The age incidence of malignancy of the periampullary region corresponds with the age incidence of malignancy elsewhere. The clinical manifestations of such conditions are usually those of common bile duct obstruction and of duodenal ulceration with bleeding and

X-RAY TIP WEIGHTED DUODENAL TUBE

Note the nine eyes, which extend for 10" so that when tube is in duodenum, drainage from the stomach and duodenum can be obtained at the same time; also that the end for 3½" is processed to appear opaque in X-ray or fluoroscopic examinations, and that the tip is weighted; thus the tube is easily carried into the duodenum. French Scale sizes 14 and 16 only. Each in box.

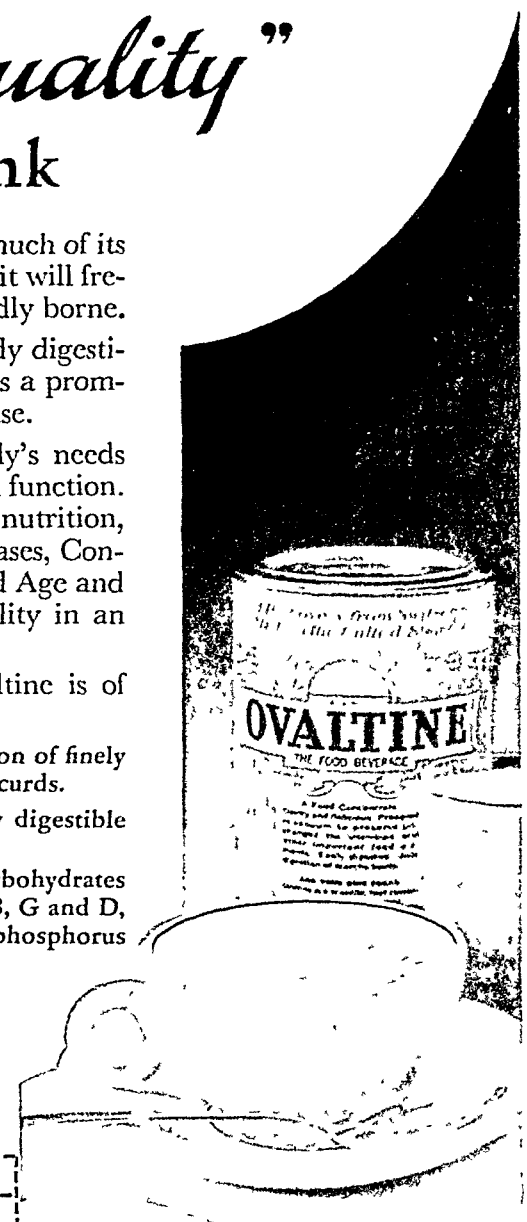
OVALTINE

"Food Quality"

in a drink

OVALTINE used as a liquid diet owes much of its reputation as an invalid food to the fact that it will frequently nourish where ordinary foods are badly borne.

Because of its high nutritive value, its ready digestibility, its palatability, Ovaltine now occupies a prominent place in the dietetic treatment of disease.



Ovaltine provides nutriment for the body's needs for energy, and material for its structure and function. It is useful in such conditions as Child Malnutrition, Fevers and Infectious Diseases, Wasting Diseases, Convalescence, Before and After Operations, Old Age and wherever it is desirable to supply food quality in an easily digested form.

There are three main reasons why Ovaltine is of value in such cases.

First, its addition to milk results in the production of finely comminuted, soft curd particles in place of tough curds.

Second, the nutrients provided are all in readily digestible form.

Third, Ovaltine reinforces milk with proteins, carbohydrates and fats. It is also a good source of Vitamins A, B, G and D, and furnishes important minerals such as calcium, phosphorus and iron.

secondary anemia. Diarrhea has been a frequent symptom.

Most carcinomas of the periampullary have been found at autopsy to be removable surgically. Death usually occurs before metastases appear. The mortality following radical extirpation of carcinoma of the periampullary region ranges between 30 and 70 per cent.

The modern one-stage operation of excision of the growth and reimplantation of the ducts carries the lowest mortality. Palliative operations whereby biliary obstruction is relieved by some anastomatic procedure between the gall bladder and upper gastro-intestinal tract, even though executed with considerable risk are often productive of much palliation.

The author reports one case of successful transduodenal resection of the ampulla of Vater for carcinoma of the distal end of the common duct and abstracts of seventeen additional cases. Seven figures, two tables and a bibliography accompany the article.

Nelson M. Percy, Chicago.

GLENN, F.

Colostomy of the Transverse Colon. S. G. O., Vol. 61, No. 5, pp. 629-634, Nov., 1935.

The author points out that transverse colostomy as an emergency operation, or as a preliminary measure in the treatment of lesions of the lower sigmoid and rectum possesses certain advantages over lumbar or inguinal colostomy. First, the bowel is always freely mobile and may be delivered into a right rectus incision with a minimum of trauma; the bowel content at that point is non-irritating to the skin. Second, a transverse colostomy is far removed from the operative field and does not endanger the asepsis of any procedure on the bowel distal to it. Peritonitis is a frequent and serious complication of procedures on the lower sigmoid and rectum.

Transverse colostomy is not a major procedure. Through a muscle splitting high right rectus incision a loop of transverse colon is elevated and held in place by means of a glass rod passed through a rent in the transverse mesocolon. The closure of the wound is designed (1) to anchor the intestine, (2) to prevent the peritoneum from tearing, (3) to isolate the rectus muscle, and (4) to avoid herniation of the bowel. The posterior leaf of the sheath of the rectus is closed and sutured to the bowel wall with medium silk sutures. The anterior leaf of the sheath of the rectus is now sutured to the peritoneum, and in the case of obese patients, the skin is drawn down to the fascia. Vaseline gauze is placed about the bowel and covered with the same type of dressing; after 36 to 48 hours the bowel is opened. If it is deemed necessary to decompress the bowel at the time of operation that may be done by introducing a needle into it after a purse string suture has been put in place. A catheter or glass tube may be inserted in the same manner. A large sized glass rod is inserted through a short incision in a tenia opposite the mesenteric attachment of the bowel, if immediate decompression is not deemed necessary. After six or seven days that tube is removed. The glass rod is usually removed before the drainage tube is withdrawn, but it may be left in place several days longer if the loop tends to retract or if it is desired to prevent any of the fecal stream from passing into the distal segment of bowel. The patient soon learns that a degree of constipation enables him to reduce the number of evacuations of his bowels to one or two a day. A dressing of absorbent material guards against soiling.

When it is desired to close the colostomy that may be accomplished by incising the skin about the colostomy, then carefully dissecting away the subcutaneous tissues and fascia until the peritoneum is seen, after which the excess tissue is cut away and the opening in the bowel closed transversely. If there has been a herniation of omentum or bowel about the colostomy, it may be necessary to deliver that part of the transverse colon outside the abdomen. Such a closure must be considered as contamination of the peritoneal cavity but peritonitis or abscess formation rarely occurs. A subcutaneous drain is recommended. After closure of the colostomy the patient is given nothing by mouth for 24 hours, then only clear fluids for 48 hours after which full diet with mineral oil may be given.

STUDLEY, HIRAM O.

Percentage of Weight Loss. J. A. M. A., Vol. 106, pp. 458-461, Feb. 8, 1936.

The surgical treatment of peptic ulcer has greatly reduced the mortality rate, especially of those cases which ruptured into the peritoneal cavity. The mortality rate has, however, not been reduced below 10 per cent in uncomplicated cases of peptic ulcer. The purpose of this article was to show the relationship between weight loss and recovery from surgically treated ulcer cases not complicated by rupture.

The weight loss was determined by subtracting the pre-operative weight from the weight before the onset of the peptic ulcer. Of fifty patients studied, the weight loss was determinable in forty-six of them. It was found that in the group whose weight loss was approximately 20 per cent, the mortality rate was 33 and one-third per cent, while in those who lost less, the rate was 3.5 per cent.

Because of the aforementioned observations, it seems that another major complication has been added to those of peptic ulcer: namely, loss of weight, and should therefore receive the indicated pre-operative preparation.

SURGERY OF THE LOWER COLON AND RECTUM

HOWET, FR. (Brussels).

Pathogenesis and Surgical Treatment of Prolapse of the Rectum. (Pathogénie et traitement chirurgical du prolapsus du rectum). J. de Chir., Tome 45, No. 6, pp. 877-908, June, 1935.

Following a study of five cases of complete prolapse of the rectum observed in the service of Lenormant, the author reviews briefly the progress made during the past 30 years in the understanding of the pathogenesis and in the treatment of this condition. According to Cruveilhier-Ludloff there are four anatomical varieties:

1. Invagination of the mucosa *(prolapsus ani)*
2. Invagination of the inferior portion of the rectum through the anus *(prolapsus ani et recti)*
3. Invagination of the superior part of the rectum into the inferior portion *(prolapsus recti)*
4. Precipitation through the anus of an invagination of the colon *(prolapsus coli invaginati)*.

Etiological data. As for hernia the etiology of prolapse of the rectum is governed by effort either single and strong (delivery), or repeated and weak (constipation), diarrhea, alternating constipation and diarrhea, irri-

CREAM of WHEAT

for Their Greater Caloric Requirements

The basal caloric requirements of a one year old infant, per kilogram of body weight, is almost twice that of an adult; that of an eight year old child is at least half again that of an adult. The continual activity of healthy children may increase tenfold the calories needed to provide for ordinary energy expenditure and normal growth * * * Cream of Wheat supplies a readily utilized and assimilated source of energy for active, growing children. Its heat treated wheat endosperm kernels are quickly digested by the pancreatic ferments; absorption takes place in a minimum length of time.

Cream of Wheat yields an average of 72.4% carbohydrate and 11.8% protein, providing a source of rapidly utilizable dextrose for high caloric requirements, and proteins for the development of solid, healthy musculature. And the palatable taste of Cream of Wheat appeals equally to infants, children, and adults. It can be eaten daily, for long periods, without tiring the appetite.

An interesting and informative brochure, "The Role of Carbohydrate Digestion and Metabolism in the Body Economy," will be forwarded to physicians on request. Please address Cream of Wheat Corporation, Minneapolis, Minnesota. Department DD 636.

tated rectum, tenesmus, hemorrhoids, intestinal worms, efforts of micturition, urethral stricture, hypertrophy of the prostate, stones in the urinary bladder, chronic cough.

Morbid anatomy of rectal prolapse. Not well understood. If the lesions of the rectum have been established with accuracy due to examination of the resected portions, those of the neighboring parts have not, except incompletely, due to a lack of sufficient autopsy material. However, two factors stand out clearly by reason of their constancy: the abnormal mobility of the rectum and the excessive depth of the pouch of Douglas. These two anomalies are essential to and characteristic of a rectal prolapse.

Pathogenesis. The pathogenesis which should be looked at from the anatomical point of view is based on two orders of facts:

1. The normal mode of fixation of the rectum;

2. The exact anatomical lesions observed in those suffering from prolapse of the rectum and, in particular, the lesions affecting the normal means of fixation of the rectum (Lenormant).

The Author observes that these two points are not yet well established and he expounds the different theories relative to the pathogenesis of these lesions. He concludes thus: "From this, we believe that to close the pouch of Douglas and to prevent all possibility of invagination of the rectum should be the two essential steps of the operative cure of rectal prolapse."

Operative treatment of the rectal prolapse. Methods of cutting off the prolapsed portion. I. *Resection by scalpel.* The Author describes the procedure most commonly employed, that of Mikulicz. He explains the different modifications of this method and the results obtained by different surgeons. This procedure, however, maintains an appreciable mortality, frequent recurrences due to the persistance of the sac and frequent strictures due to suturing. These three arguments condemn the resection (Lenormant). The Author concludes that in view of the serious consequences which may ensue it is unwise to resect the prolapsed rectum, except: (1) When it is irreducible or (2) when there is danger of introducing in the pelvic cavity a septic focus *e. g.* where the rectum is gangrenous or very ulcerated or where there is a strangulated hydrocele.

II. *Method of keeping the reduced rectum in place.* The theories of pathogenesis have served as the basis of these methods.

1. Procedures to reconstruct the pelvic floor: (a) Shortening or contraction of the sphincter ring; (b) Substitution of the sphincter by the method of Thiersch; (c) Strengthening of the sphincter by strips of muscle; (d) Myorraphy of the *levatores ani;* (e) Muscular or aponeurotic strips strengthening the pelvic floor.

These different methods are reviewed and commented upon.

2. Procedures which have for their aim the suspension of the rectum:

(a) Rectopexy (posterior and lateral); (b) Colopexy; (c) Fixation of the pelvic colon to the anterior abdominal wall; (d) Fixation of the pelvic colon to the pelvis.

3. *Procedures of which it is the aim to efface the pouch of Douglas* (notably the method of Moscowitz):

Then the Author, in more than three detailed pages, give the results of the operation which has for its object the suspension of the rectum.

III. *Resection of the mucosa only* (Procedure of Delorme-Juvara).

Technique, advantages and inconveniences of the method are clearly set forth.

The last chapter deals with the choice of operation with special reference to the general condition of the patient and the local condition.

Cases where resection by the scalpel is the only traetment possible:

1. Irreducible collapse; 2. Strangulated rectum; 3. Strangulated hadrocele; 4. Extensive and deep ulceration of the rectum; 5. Stricture; 6. Invagination by malignant tumor.

Outside of these eventualities, resection should not be employed because of the immediate danger of hemorrhage and infection, especially of stricture, even after several months.

When the prolapse may be reduced without danger, three methods are especially recommended:

Colopexy of Quénu and Duval is the most nearly perfect and the least dangerous, to be completed, in case of need, by a posterior perineorrhaphy and by the silver wire encircling of the anus. If laparotomy is contraindicated is it necessary to limit oneself to a less shocking perineal operation and to employ the technique of Delorme-Juvara? If the physical or psychic state of the patient prohibits the use of this latter procedure, one may do the encircling of the anus with metal wire under local anesthesia.

The Author presents thirteen unpublished observations, 5 colopexies, 3 operations employing the Delorme-Juvara technique, 5 encircling of the anus. A detailed bibliography completes the work.

Pierre Smith and Thomas Farmer,
Montreal, Canada.

TAXOL

SUGGESTION No. 5

Dear Doctor:

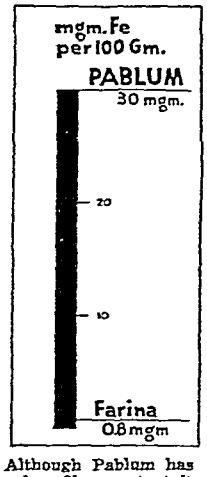
Every physician is called upon to diagnose and treat many of the more simple conditions where a history or more or less chronic constipation is a contributing cause.

A recent, or an old, case of clogged bowels with facial acne, pustulous or not, is a case in point. If such a condition is referred to a specialist, or treated in your office, prepare it first by prescribing TAXOL, one or two b.i.d., or more, until the function of the bowels is well regulated.

If this skin condition is due to stasis it is quite possible that a remarkable clearing of the acne may be noticed.

Samples of TAXOL for clinical tests are available on request. Please write.

Very truly yours,



LOBICA LABORATORIES
1841 BROADWAY
NEW YORK

LOBICA LABORATORIES, 1841 Broadway, N.Y.C.
I would like a supply of TAXOL, also literature.

For bland diet therapy, especially ULCER cases—PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastro-intestinal disorders is a deficient diet. An analysis made by Troutt of ulcer diets used by 6 leading hospitals in different sections of the country showed them to be "well below the Sherman standard of 15 milligrams" in iron and low in the water-soluble vitamins.[1] "Vitamin B would appear to be represented at a maintenance level in most cases," writes Troutt, "but the possible relation of vitamin B to gastro-intestinal function and appetite should make one pause before accepting a low standard."

Although Pablum has a low fiber content it is 37 times richer than farina in iron and in calcium, 4 times richer in phosphorus, and 4½ times richer in copper.

Low in Fiber—High in Iron

Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastro-intestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than farina and is an excellent source (+ + +) of vitamins B and G, in which farina is deficient. Supplying 8½ mgms. iron per ounce, Pablum is 8 times richer than spinach in iron.

Rich in Vitamin B

The high vitamin B content of Pablum assumes new importance in light of recent laboratory studies showing that avitaminosis B predisposes to certain gastro-intestinal disorders. Apropos of this, Cowgill says, "Gastric ulcer is another disorder which can conceivably be related to vitamin B deficiency. Insofar as the treatment of this condition usually involves a marked restriction of diet the occurrence of at least a moderate shortage of this vitamin is by no means unlikely."[2]

Requiring no further cooking, Pablum is especially valuable during the healing stage of ulcer when the patient is back at work but still requires frequent meals. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Pablum has the added advantage that it can be prepared in many varied ways—in muffins, mush, puddings, junket, etc. Further, Pablum is so thoroughly cooked that its cereal-starch has been shown to be more quickly digested than that of farina, oatmeal, cornmeal, or whole wheat cooked four hours in a double boiler (studies *in vitro* by Ross and Burrill[3]). In addition to the above advantages, Pablum is the only base-forming cereal (except Mead's Cereal which is the uncooked form of Pablum).

Pablum (Mead's Cereal thoroughly cooked) consists of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa, yeast, beef bone, iron salt and sodium chloride. [1-3] Bibliography on request.

BILE SALTS

Fairchild

The sodium glycocholate and taurocholate, the salts of conjugated colic acids in their native association as separated from fresh ox gall.

A stable dry powder; uniform in composition; efficient for the well known therapeutic uses of ox-gall—in disorders due to faulty bile functioning.

Bile Salts preferably to be dispensed in capsule by itself, or in combinations in powder.

Offered in powder, ¼ oz., 1 oz. vials; in capsules, each three grains Bile Salts.

Fairchild Bros. & Foster
New York

EXICOL

INDICATED in hepato-biliary disorders when dependable cholagogue and choleretic action is desired.

In prescribing Exicol you have the advantage of an effective therapeutic agent checked in the animal laboratory and clinically.

Exicol therapy is based on latest known and accepted physiologic principles governing the biliary apparatus.

ACTION: 1. It stimulates gall bladder evacuations (Cholagogue) and
2. Increases bile flow from the liver (Choleretic).

DOSE: 2 capsules t.i.d.a.c.

In boxes of 36 and 100.

SECTION I—*Clinical Medicine: Diseases of Digestion*

The Use of Chondroitin in Idiopathic Headache (Including Migraine)*

By

LATHAN A. CRANDALL, Jr., M.D., Ph.D.
GEORGE M. ROBERTS, M.S., M.D.
and
LOWELL D. SNORF, M.D.
CHICAGO, ILLINOIS

THE use of chondroitin (chondroitin sulphuric acid) in the treatment of idiopathic headache of the migraine type was made the subject of a preliminary report in 1933 (1). This study has been continued and extended to include data on 151 patients over a maximum period of 3 years. Our results warrant discussion on two grounds: first, the demonstration that chondroitin exhibits a definite physiologic action; second, the possibility that this substance may prove to be of therapeutic value in prevention of idiopathic headache, a field in which treatment is too frequently unsatisfactory.

Our interest in the action of the carbohydrate fractions (prosthetic groups) of the mucoproteins was aroused by the apparent systemic effect of mucin in certain experimental animals. Since such an action could hardly be attributed to the protein fraction of mucin, we attempted to prepare mucoitin (the prosthetic group of mucin). But mucoitin is difficult to prepare in quantity, whereas chondroitin (the very similar carbohydrate group of chondromucoid) can easily be made in large amounts. We therefore studied the action of chondroitin in patients with "peptic" ulcer, and found some evidence of beneficial action (2). Certain of these ulcer patients complained of headache of the migraine type, and the administration of chondroitin seemed to reduce the frequency and severity of the headache to a marked degree. We therefore continued with the study of chondroitin in uncomplicated idiopathic headache.

Chondroitin sulphuric acid is a definite chemical compound composed of 2 molecules of glucuronic acid, 2 molecules of galactosamine to which acetyl radicals are attached, and 2 sulphate groups. Its chemistry is discussed by Levene (3). In order to be able to prepare large amounts for administration to patients it was necessary to develop a simple method of preparation which avoided the use of barium or other toxic materials. The method used consists essentially of extracting cartilage with 2% sodium hydroxide, neutralizing the alkali, and precipitating with alcohol. Material so prepared contains a certain percentage of impurity. For approximately 1 year it was purified by precipitation with glacial acetic acid; more recently we have been using a product which contains approximately 25% of impurity (chiefly salts and protein)†. The clinical results with the less pure preparation are entirely comparable with those obtained with the purified product. The amount of chondroitin sulphuric acid present has been determined by analyzing for glucuronic acid (4). Sulphate analyses have indicated that the theoretical amount of sulphate radical is not present. The product therefore is actually a mixture of chondroitin sulphuric acid and chondroitin. We have preferred to use the latter term since it is equally descriptive.

THE USE OF CHONDROITIN IN IDIOPATHIC HEADACHE

We have purposely included in our series all available cases of headache which could not be ascribed to a known cause. Although a more or less definite syndrome termed migraine is generally recognized, we are totally ignorant of its etiology and it is impossible to say whether those headaches which do not present the classical features of migraine are nevertheless on the same basis, whether classical migraine forms a group by itself, or whether there may be more than one cause of migraine and that we may therefore be using this single term for more than one entity.

For purposes of study in this field it is highly desirable to set up rigid criteria, in so far as possible, in order that similar cases may be studied by various workers. We have therefore classified as migraine only those patients having: (1) Both a family history of periodic headache and a definite periodicity in the patient for a term of years; (2) Having at some time 2 of the following 3 characteristics: (a) aura (b) nausea and or vomiting (c) unilateral headache.

Others have noted the tendency for nausea and vomiting to play a predominant part in the picture when the attacks of migraine begin in childhood, and for these symptoms to become less and less prominent with advancing years. We have further noted, and have verified our observation by discussion with others, that as attacks of typical migraine become more and more frequent as the patient reaches middle life there is a tendency toward the development of frequent, perhaps daily, headache of a different character. A number of patients who have characteristic attacks of migraine

occurring perhaps every 7 or 14 days also complain of less severe headaches, not preceded by an aura or accompanied by nausea or vomiting, which may be much more frequent to the point of being present constantly. Such atypical headache, occurring in patients with migraine, we have termed "interval headache" for purposes of description. In patients presenting typical attacks of migraine interspersed with atypical "interval" headaches, both types of headache have ordinarily improved to about the same degree whenever there has been a response to any form of treatment.

Patients with headache which does not fulfill all of the criteria for migraine but who have idiopathic headaches of the migraine type we have grouped under the classification "migrainoid." The majority of our cases are dispensary patients and in some instances

information concerning the incidence of headache in the family is lacking, or there may be a positive family history and definite periodicity of the headache with nausea and vomiting but bilateral pain and no aura. Such cases might be presumed to be migraine, but they verge gradually into the type in which bears no resemblance to classical migraine. This last group, which we have termed "simple idiopathic headache" exhibits little more than head pain which may be constant or periodic. The chief merit of such a classification is to distinguish those patients who unquestionably exhibit the migraine syndrome, so that a comparison of our results with those of others is possible.

The treatment of idiopathic headache with the purified chondroitin first employed was carried out as previously described (1). The material used during the last 2 years must be given in somewhat larger dosage because it contains approximately 25% of inert

material. We begin routinely with 4 capsules (8 grains each) 3 times daily before meals and continue this dosage until some impression of the response of the patient is obtained. If after the first month or two the result is not satisfactory, the dosage may be increased to 18 or 24 capsules daily. Our experience indicates that the division of the daily dose into 3 parts taken before meals is not essential. It is essential that the patient take the full number daily. We have not suggested a reduction in dosage until a thoroughly satisfactory response has been maintained for a period of several months; the number taken daily may then be decreased in some instances although we have no cases in which fewer than 6 capsules daily are necessary to prevent the attacks.

Because of the well known tendency for patients with migraine to improve temporarily when placed on any new form of therapy a number of the patients who had responded satisfactorily to chondroitin were given similar capsules containing calcium lactate and were not informed of the change. Others were started on calcium lactate in this form and continued on such a placebo for 1 month. Not all patients who discontinue chondroitin have a prompt recurrence of attacks. Therefore the substitution of calcium lactate in those cases on treatment did not always result in exacerbations. Where the attacks did recur there was again a prompt improvement when chondroitin was again given. When 15 patients were given calcium lactate in capsules as their first medication, 8 reported marked improvement when chondroitin was substituted without their knowledge of the change. Another control of the psychogenic factor was unwittingly carried out when a change in the method of preparation of the chondroitin resulted in an inactive product. We were not aware that the new product was ineffective until the patients on treatment at the time reported recurrences; when given chondroitin made by the standard process these patients again reported satisfactory results.

Tables I, II, and III show the results obtained by the administration of chondroitin in cases of migraine, migrainoid headache, and simple idiopathic headache respectively. The patients were not selected, except that each was carefully examined to exclude possible known causes of headache. Of the patients exhibiting apparent benefit none are included who have been under treatment for less than 4 months. In those showing no improvement the administration of chondroitin was continued for at least 2 months, since the response in some cases is slow. Success of the treatment was estimated by the change in frequency and severity of the attacks. The headaches were graded *severe* if the patient was completely incapacitated, *moderate* if able to be up and around but not able to engage in ordinary activity, and slight if they were not troublesome.

It is interesting to note that between 45 and 50% of patients in each of the 3 groups obtained satisfactory relief from their attacks. This suggests that there may be no essential difference in the etiology of idiopathic headache whether it manifests itself as typical migraine or as simple headache without the characteristics of the migraine syndrome. We consider that satisfactory results have been attained when the patient has so few or such slight attacks that they are no longer a source of annoyance and would not lead him to consult a physician. Actually many of these individuals have had no attacks during the course of treatment. However, we have observed that patients who have progressed satisfactorily for 4 to 8 months without any headache may have an attack as the result of psychic trauma. Headache in such instances has followed the death of the husband, loss of the home by fire, loss of employment, marital difficulties, etc. After attacks so precipitated the patient will ordinarily be headache free for a further long period. Such cases are considered to have had as good a result as those who remain completely free from headache for long periods in the absence of any outstanding mental or physical upset. It is apparent that the administration of chondroitin acts to "increase the headache threshold," rather than to remove completely the underlying cause.

Patients in whom the response is classified as "fair" have reported at least a 50% reduction in frequency or severity; in case of question as to the percentage decrease they are termed not relieved. Patients with a "fair" result are often most grateful, since many of them have failed to obtain any benefit from other forms of treatment.

No untoward effects have been observed as a result of the continued administration of large amounts of chondroitin to patients or experimental animals, with the exception that some individuals may report an increase in flatulence which as a rule subsides within the second week. Where the flatulence is associated with an "irritable bowel" chondroitin in a few cases may produce enough distress to be troublesome. Complete elimination of starchy foods and uncooked fruit or vegetable from the diet will usually make it possible for these cases to remain symptom-free on chondroitin. Where such dietary measures have been introduced chondroitin has been discontinued and the effect of the diet alone has been ascertained. In some instances such a dietary regime produces improvement, but very rarely satisfactory relief.

A marked subjective sense of improvement has been reported by a number of individuals who previously complained of a constant sense of fatigue. Such a response is most difficult to evaluate and is only mentioned because so often spontaneously described by the patients. This increased sense of well-being usually accompanies relief of headache and may therefore be due to the absence of periodic incapacitation. However, it may be so striking as to suggest that it is not secondary to freedom from attacks, and is occasionally seen in patients that report only slight improvement in headache. It may be accompanied by an increase in appetite; a number of patients have gained weight.

When the daily administration of chondroitin is discontinued many patients remain headache-free for a considerable period of time. In fact, 2 have reported intervals of more than 9 months of freedom after taking chondroitin for only 4 weeks; these cases are not included in our series, since such an exceptional result leads us to suspect a psychogenic factor. In the majority of patients there is a recurrence of the typical symptoms within a few weeks after discontinuing the therapy. Some may have an attack if they omit their regular dosage for even 1 or 2 days. In a number of patients who have been on treatment for several months the attacks have not returned for 3 to

6 months after discontinuation, and have then been present in a mild form.

OTHER OBSERVATIONS ON MIGRAINE

In patients not relieved by chondroitin we have used various methods of treatment suggested by others. We have also employed certain laboratory procedures in the hope of finding some method of classifying these cases. Certain observations on such findings in the group presenting the classical symptoms of the migraine syndrome may be of interest.

Methods of treatment other than chondroitin have included diet, calcium lactate, "Emmenin," "Theelin," sodium thiosulphate, ergotamine, and pituitrin. Our dietary measures have been confined to prescribing a bland diet low in starch and containing a high proportion of cooked fruit and vegetable in cases with carbohydrate intolerance and flatulence. Occasional improvement results from such management but the result is rarely entirely satisfactory. Calcium lactate alone or in combination with diet has proven to be of little benefit. "Emmenin" and "Theelin" have been used where the attacks seemed to be related to the menstrual period; "Emmenin" has given good results in 2 out of 10 cases, "Theelin" in about the same proportion. Sodium thiosulphate given by intravenous injection in 1 gram doses twice weekly has usually failed when chondroitin has failed, but has further improved some patients who had obtained only a fair response with chondroitin. We have seen a number of patients who have previously been given ergotamine. These cases, as well as those in which we ourselves have used this alkaloid, have responded promptly to subcutaneous injection although administration by mouth has been of little benefit; similar results are reported by others. It should be pointed out that ergotamine may so greatly increase the nausea, even though the headache is abolished, that the patient refuses its use. Pituitrin, 0.5 c.c. subcutaneously given early in the attack, has caused a cessation of all symptoms in a number of cases.

Our laboratory determinations have been of no assistance in the classification of cases. In confirmation of previous reports, we find an elevated plasma cholesterol in approximately 50%; this finding is not as a rule present when the headache can be ascribed to known causes but is not sufficiently consistent in migraine to be of value. Serum calcium determinations in 25 patients with classical migraine have given only normal values. Beazell and Crandall (5) have found the purine bodies of the blood to be within normal limits both during the attacks and in intervals of freedom; they have also been unable to confirm (6) the reported decreased output of female sex hormone in the urine. Quantitation of the urinary sex hormone is so unsatisfactory at the present time that we question whether such studies can yield significant results. In some cases of migraine the basal metabolic rate tends to be low or at the lower limit of normal; this finding is perhaps even more common in idiopathic

TABLE IV

Summary of Results

	Satisfactory	Fair	Less than 50% Improvement
Migraine 83 patients	41 (49.4%)	20 (24.1%)	22 (26.5%)
Migrainoid 47 patients	23 (49%)	11 (23.4%)	13 (27.6%)
Non-migrainous 19 patients	9 (49.4%)	4 (21%)	6 (31.6%)

headache not of the migraine type. Administration of thyroid in such cases has been of benefit.

MECHANISM OF ACTION OF CHONDROITIN

At present the most significant conclusion to be drawn from our results is: chondroitin produces a definite physiological effect on oral administration. Whether or not chondroitin proves sufficiently useful to be added to the list of agents which deserve trial in the individual case of idiopathic headache, the demonstration of its action in any percentage of cases opens a new field. No physiological action of chondroitin or any of its constituents has been demonstrated previously. Little is known of the metabolism of glucuronic acid in the body, less concerning glucosamine or galactosamine. We do not now have sufficient evidence on which to base a satisfactory theory which will explain the action of chondroitin, but certain studies which have been made may be recounted.

In order to determine whether chondroitin might cause improvement in migraine by altering conditions

TABLE VI

Sex Distribution of Patients

	Migraine	Migranoid	Non-migrainous
Males	29%	25.5%	68.5%
Females	71%	74.5%	31.5%

in the gastro-intestinal tract, its effect upon the bacterial flora of the stool and upon the secretion of bile have been studied. As stated in our preliminary report (1), Crandall and Lederer found no change in fecal flora when large doses of chondroitin were administered to normal individuals. Stinchfield and Crandall (7), using bile fistula dogs, found no change in biliary output following oral administration of chondroitin although the general condition of the animals seemed to be improved.

Further evidence of systemic action has been obtained from a study of the effect of mucin and chondroitin in Eck fistula dogs by Crandall, Roberts, and Gibbs (8), who reported weight gains and improved general nutrition in these animals which ordinarily maintain their weight at about 25% of the preoperative level. Gibbs and Crandall (9) have further studied the protective action of chondroitin when given to dogs together with cinchophen. Animals receiving 100 mgm. cinchophen per kilo per day ordinarily die in 1 to 3 weeks with evidence of marked liver damage and acute gastric or duodenal ulcers. When chondroitin is added to the diet of such animals the length of life is approximately doubled and the ulcerative processes become much more chronic.

It has long been known that certain toxic substances are excreted in the urine in combination with glucuronic acid. The body manufacturers this substance, presumably in the liver. It is not known whether a deficiency of glucuronic acid ever occurs. The evidence thus far, however, suggests that the liver is concerned in whatever metabolic changes are brought about by the administration of chondroitin. Since we have given other products which contain glucuronic acid but no glucosamine or galactosamine and have obtained some benefit in idiopathic headache (1), it appears more probable that the glucuronic acid fraction of chondroitin is active than that the effectiveness of chondroitin is due to its amino-sugar content.

SUMMARY

Since the publication of a preliminary report on the use of chondroitin (chondroitin sulphuric acid) in 42 cases of idiopathic headache, a continuation of the study has made possible the compilation of data on more than 150 cases. The longest period of observation has been 3 years. Patients who showed no improvement have been observed for at least 2 months, those who reported benefit have been followed for 4 or more months.

Chondroitin (obtained from cartilage) contains glucuronic acid, glucosamine, and sulphate radicals. The material used has been a commercial extract approximately 75% pure.

The majority of cases treated have been of the migraine type. In approximately 50% of all instances

TABLE VII

Correlation of Response in Migraine with Age, Sex, and Frequency of Attacks

	Age		Sex	
	Over 35 (35 patients)	Under 35 (47 patients)	Males	Females
Satisfactory	57%	40.5%	41.6%	52.5%
Fair	29.6%	23.4%	20.8%	25.4%
Less than 50% improvement	14.4%	36.1%	37.6%	22.1%

	Frequency	
	Average interval between attacks 10 days or less (51 patients)	Average interval between attacks more than 10 days (32 patients)
Satisfactory	41.0%	65.6%
Fair	29.5%	15.7%
Less than 50% improvement	29.5%	18.7%

the results have been satisfactory; i.e., headache, when it persisted, was not severe enough to be troublesome. In another 20% the frequency or severity of the attacks was reduced at least 50%.

Whether chondroitin will be found useful by the medical profession in the treatment of idiopathic headache can only be determined by the test of time. A point of immediate interest is the demonstration of the physiological effect of this complex carbohydrate, concerning which so little is known. The possible mechanisms of its action are discussed.

The Gastro-Intestinal Symptoms in Hypertension*

By

S. KENNETH ROBINSON, M.D.

CHICAGO, ILLINOIS

IN a clinic where a large number of gastro-intestinal patients is seen, one cannot help but be impressed with the number who also have hypertension. The question arises whether these digestive complaints are not in some way related to the hypertension and its concomitant cardiovascular or neurogenic phenomena, or whether they are purely accidental and unrelated. It is recognized that hypertension is associated with nervous instability (1-2), vasomotor disturbances (2), migraine (2), colitis (2) and hyperthyroidism (3-4-5-6-7-8-9). It is also recognized that some of these conditions may give rise to gastro-intestinal symptoms (10-11).

The present report consists of a study of 60 consecutive hypertensive patients whose systolic blood pressure reached 160 m.m. of Hg, or the diastolic 95 m.m., or in whom a hypertensive heart was found at autopsy. Fifty-one of these patients had digestive complaints during life; the other nine had some alimentary tract lesion of importance which was discovered at operation or at autopsy.

There were 25 males and 35 females, the *age* grouping was as follows:

Third decade 4, Fourth decade 9, Fifth decade 15, Sixth decade 12, Seventh decade 17, Eighth decade 2, Unknown 1.

The most frequent symptoms and signs were: epigastric pain or distress 23, constipation 18, abdominal pain 16, belching 13, nausea and vomiting 11, melena 7, jaundice 5, right upper quadrant pain 5, diarrhea 4, anorexia 4, pressure against the heart 3, "indigestion" 2, right lower quadrant pain 2, fullness in epigastrium 2, weight in the stomach 1, left lower quadrant pain 1, and a cold feeling in the epigastrium 1. It was found on dividing these symptoms according to sex that the females complained more frequently of belching, constipation, and abdominal pain whereas the males complained more of epigastric pain.

A classification of the *diagnoses* which occurred two or more times was made. This divided the cases into two main groups, chronic and acute, with subgroups as shown in Table I. It was found that 85 per cent of all the 60 cases could be included in this classification.

THE CHRONIC AFFECTIONS

Ulcer: There were 10 cases, including 2 perforated, with a definite diagnosis of ulcer by X-ray examination or at autopsy. Two of the cases of gastric hemorrhage were most probably due to ulcer, since cancer and cirrhosis of the liver, the two other most common causes of gastric hemorrhage, could be excluded by the long course of the disease and the physical findings. This would give a total of 12 ulcer cases, an incidence of 20%. Among the males there were 8 cases; and since there were 25 males, the incidence was 32 per cent. There were four other cases with

*From the Department of Medicine, Michael Reese Hospital, Chicago, Ill.

Submitted January 6, 1936.

pain quite characteristic of ulcer, but in whom the X-ray pictures were either negative or not taken.

Colitis: Under colitis were included 9 cases. These patients had such symptoms as belching, constipation, or diarrhea or both, melena, abdominal pain, and mucus in the stools. Often they showed also a spastic colon when X-rayed. As sub-groups of colitis there was one case of diverticulitis and one case of melena, which probably represented some form of colitis. Constipation was the sole complaint in 4 cases, otherwise when it occurred it was not the outstanding symptom and was usually associated with colitis.

Gastrocardiac Syndrome: There were nine cases listed under gastrocardiac syndrome. In this condition, the epigastric pain was usually found dependent upon or closely associated with symptoms of a weakened myocardium. Although this syndrome has been recognized for a long time and its significance properly interpreted, still, every once in a while, it is mistaken for gall bladder disease. Attention should therefore be called to it because it may frequently be relieved by small doses of digitalis. The distress was always in the upper abdomen and radiated upward to the sternum, chest or left arm. The distress was brought on or aggravated by exertion. Complaints such as shortness of breath or other complaints pointing to a weakened myocardium were common. Flatulence with eructations of gas was also a very frequent complaint. The primary cause for this condition is not clear, but the relief obtained from digitalis points to the cardiac condition as primary. However, Roemheld thinks that these symptoms are caused by distention of the stomach, by elevation of the left leaf of the diaphram, which is more mobile than the right, and also by reflex caused by toxic products of digestion. The following cases are representative of this group:

Case I: A female, 68 years of age, complained of gastric distress, nausea, and constipation. There was no actual pain and the distress was not related to meals. She also complained of weakness, loss of weight, and shortness of breath.

On examination, the lips were cyanotic; there was a systolic murmur at the apex and edema of the ankles. The blood-pressure was 170/90. X-ray examination of the stomach and duodenum was negative. The gall bladder showed faint concentration of the dye but no stones. The stools contained no blood or mucus. On small amounts of digitalis her dyspeptic symptoms disappeared. Comment: The cardiac picture is so prominent in this case that it is reasonable to believe that the gastric distress and nausea are in some way related to it, and the response to digitalis substantiates this belief.

Case II: A colored female, 48, complained of "misery" in the epigastrium radiating under the sternum, also dyspnea. She stated that gas accumulated in her stomach, pressed against her heart and made her heart beat fast. The heart was enlarged and the sounds were feeble with a systolic murmur at the apex. The blood pressure was 174/94. On small doses of digitalis, the alimentary tract symptoms were relieved.

Gall Bladder Disease: There were 5 cases included under the heading of gall bladder disease; of these, two had typical colic and stones were demonstrated in the gall bladder. In the remaining 3 cases, gall stones were found at autopsy; but it could not be said with certainty that the stones were the cause of the gastro-intestinal complaints, since the symptoms were atypical for gall bladder disease.

Gastric Neurosis: The diagnosis of gastric neurosis was made three times. The tendency is to use this as a last resort diagnosis when no organic lesion can be found in the abdomen. However, Dorfler (12) has described a rather definite group of digestive symptoms, to which he applied the term 'magen neurose'; the description was found to fit 3 cases in this series very well. The syndrome is characterized by pain in the epigastrium which is worse at night but better in the morning. Nourishment eases the pain. There is very little if any vomiting, but belching is common and is followed by relief. The bowels are regular or there may be alternate constipation and diarrhea. The patient usually has no difficulty in eating such foods as cabbage, radishes, carrots, etc. On palpating the abdomen, there is tenderness at every point of pressure. The patient is usually a blooming, well nourished person who also complains of other nervous symptoms such as palpitation, sleeplessness, cold feet, blood rushing to the head, headache, etc.

THE ACUTE SYMPTOMS

The acute symptoms were of a sudden onset, severe, often violent and associated with hemorrhage or rupture of a viscus. The first of this group comprised six cases called 'uremia syndrome' for want of a better name. The symptoms are ushered in with severe nausea and vomiting, with or without abdominal pain. The CO_2 combining power of the blood and the N.P.N. are usually elevated, and the blood chlorides may be reduced. There is headache; the patient becomes drowsy, then comatose; the disease runs a rapid downhill course and *exitus* is from what appears to be uremia. In some instances, however, the renal symptoms are in the background; and just before death, the cerebral manifestations are most evident. Two cases are cited:

Case I: A male, 66, was brought to the hospital because of continuous vomiting for 3 days, which he thought came on after eating canned apples. There were also abdominal pain, constipation, rigidity of the abdomen with signs of intestinal obstruction. The temperature was 101° and the B.P. 198/130. He improved and the signs of obstruction cleared up. Several days later, before he left the hospital, he became drowsy, irrational, dyspneic, the N.P.N. rose to 120 mg. per cent and he died in uremia.

Comment: The canned apples may have had nothing to do with these symptoms, and this represents an acute episode that can occur in the course of hypertension. However, even if the apples were the exciting cause, such a severe clinical picture is uncommon. Apples do not usually cause severe poisoning; and if botulism can be excluded, as it can in this case, recovery is the rule. The fact that the symptoms were so severe and terminated fatally shows an extreme degree of sensitivity in this patient.

Case II: A male, 58, was brought to the hospital because of sudden severe nausea and vomiting and coughing which had lasted a week. Up until this illness he had always been well. His temperature was normal and the blood pressure 210/150. The urine showed large amounts of albumin and at no time did his temperature exceed 99.6°. Edema and effusion in the pleural cavities developed rapidly, followed by anuria. He became restless and died

the next day, eight days after the onset of the nausea and vomiting.

Some of these cases do not terminate in uremia and the N.P.N. may remain normal, as a matter of fact the uremia, *per se*, may only be a terminal or incidental finding of some more general disturbance. Eppinger, *et al* (13) have described a similar syndrome which occurs after the ingestion of spoiled meat. There are nausea, vomiting and collapse, with signs of peritonitis. The temperature is usually low but may be elevated, the urine shows albumin, urobilin, acetone, indican and casts. At autopsy, the stomach mucosa is thickened, dark, with small erosions and ulcerations. They are more pronounced in the duodenum and large colon. The liver shows the typical picture of 'serous inflammation' as described by Rössle. The other parenchymatous organs are large and water-logged. Bordcley (14) has shown that a similar clinical syndrome terminating in uremia can occur after blood transfusion. The uremia following in the wake of severe burns when the partially decomposed skin proteins gain access to the blood stream is well known. It is possible that the 'uremia syndrome' herein described is similar to those described by Eppinger *et al* and Bordley and that a reaction of an allergic nature may be at the bottom of this syndrome. Persons with hypertension would probably be more subject to such manifestations than are normal persons since, as was previously shown, they are liable to have ulcers and other lesions in the alimentary canal which would allow partially split proteins and other toxic products of digestion to gain ready access to the blood stream.

Gastric Hemorrhage: Gastric hemorrhage occurred three times. Two of these patients complained of epigastric distress and one of these had a peptic ulcer. The third had no symptoms other than the hemorrhage. Perforated peptic ulcer occurred twice and hemorrhage into the pancreas occurred once.

Miscellaneous Cases: There were seven miscellaneous cases; the liver was the seat of the disease in four of these. Parenchymatous degeneration of the liver, carcinoma of the liver, cholangitis with liver abscess, and alcoholic fatty cirrhosis were observed once each. Intestinal tuberculosis occurred once; and gangrene of the ileum was observed once, at autopsy. The last case was one of recurring abdominal pains; these pains occurred several times a day, usually after meals.

Hyperthyroidism: It is significant that a large number of these patients showed some signs of hyperthyroidism, no less than eleven patients showing such symptoms. Among these, the diagnoses of colitis and ulcer were most frequent, occurring 4 and 3 times respectively. Constipation also occurred 5 times and diarrhea once. Because of this overlapping, hyperthyroidism was not included as a special heading in the table. There were 7 females and 4 males and all but two were over 40 years of age, five occurring in the sixth decade. The B.M.R. was done in all cases but one and ranged from 1.4 plus to 50 plus.

DISCUSSION

The high incidence of peptic ulcer in this series deserves some comment. According to Cabot (15) in approximately 16,000 patients, both with hypertension and normal blood pressure, who presented themselves with abdominal complaints, the incidence of peptic ulcer was 9.3 per cent. In this series, the incidence was 20 per cent which suggests that there may be more than an accidental relation between peptic ulcer and hypertension. Kylin (1) is of the belief that peptic ulcer is common in hypertension. He states that as the K/Ca ratio in the blood rises, such diseases as nervous disorders, hypertension, and ulcer become more frequent. Kylin (2) also states that the hypertensive patient is likely to have diabetes, asthma, gout, vasomotor disturbances, colitis, and migraine. Wechsler (16) in a very illuminating article on abdominal pain as a symptom of disease of the brain, quotes Cushing's series of 9 cases of interbrain lesions with peptic ulcer, two of which also had malignant hypertension.

Of considerable importance is the fact that cancer was a rare lesion in this series. Cancer of the stomach was not observed at all; and cancer of the bowel was seen one time, an incidence of 1.7 per cent. According to Cabot's figures, the incidence should have been 6 and 3.9 per cent respectively.

Colitis occurred 9 times, an incidence of 15 per cent; this is high also. Cabot does not even list colitis in his series.

It is of interest that the abdominal pains so frequently seen in tuberculosis were observed only once in this series. In Cabot's series, they were second on the list with an incidence of 12 per cent. Evidently hypertension, so rare in tuberculosis, serves to exclude that disease.

The fact that about 85 per cent of all the cases in this series fall into the simple classification given in the Table should be of help in the differential diagnosis of abdominal symptoms, if hypertension is present. If the symptoms are of a chronic nature, ulcer and colitis should be first considered; these two conditions made up about 50 per cent of all the chronic cases. The gastrocardiac syndrome should be easy to recognize; and if all of these are absent, then a careful investigation of the gall bladder should be made. If the symptoms are acute then we should think of the uremia syndrome, perforated peptic ulcer, gastric hemorrhage, or some similar vascular accident. Severe vomiting, weakness, headache, and sleepiness in a person with hypertension should direct attention to an impending uremia.

The association of the three conditions, *i.e.* hypertension, hyperthyroidism, and a lesion in the alimentary canal, such as colitis or ulcer, was seen seven times which suggests that there must be some relation between them. A nervous or circulatory disturbance of some kind is probably behind this triad; it may be of the nature of a neuro-vegetative imbalance. A discussion of this highly theoretical subject is beyond the scope of this paper.

SUMMARY

1. In the 60 cases of hypertension also having gastro-intestinal complaints, peptic ulcer occurred 12 times, an incidence of 20 per cent. This high incidence suggests a possible relation, but the series is too small to draw any definite conclusion.

2. Colitis was also frequent, it occurred 9 times, an incidence of 15 per cent.

3. Hypertension, hyperthyroidism, and a lesion in the alimentary tract such as colitis or ulcer occurred together 7 times. This strongly suggests that the concurrence of these three conditions is not accidental but that they are related and that some general disturbance of a circulatory or nervous nature is responsible for this triad.

CONCLUSION

It is reasonable to conclude that the gastro-intestinal symptoms seen with hypertension are to a considerable extent conditioned by the cardiovascular, neurovegetative, and other phenomena concomitant with the hypertension.

Tobacco Sensitivity in Peptic Ulcer*

A Second Report

By

IRVING EHRENFELD, M.D.

and

MILLS STURTEVANT, M.D.

NEW YORK, NEW YORK

IT has been a clinical impression among the workers in the Subclinic of this Clinic that patients affected with peptic ulcer do not respond to the routine ambulant treatment if they continue to smoke tobacco. For the last nine years it has been the custom in the Clinic to advise such patients against smoking.

Our experience in accordance with that of other observers, so much so that tobacco smoking has even been thought to have a part in the pathogenesis of ulcer (1, 2, 3, 4). There has been reason to think that tobacco smoking raised gastric acidity (3, 5, 6), and affected gastro-duodenal motility (7, 8). It might be suspected that the action of the tobacco was through the effects of nicotine (9, 10, 11, 12) on the autonomic system (13) by means of secretory and motility phenomena (14, 9).

In 1932, Harkavy, Hebald and Siebert (15) reported that intradermal injections of extracts of Burley, Virginia and Xanthis tobacco showed patient sensitivity to one or more of the extracts in 83% of a series of 68 cases of thrombo-angiitis obliterans. In 1933, Harkavy (16) gave his results of similar tests of cases of disease of the blood vessels and 281 controls. Among the latter he found that of 60 cases of gastro-duodenal ulcer, 16 cases, (26%) were sensitive to tobacco. Eleven of these had either a personal or family history of allergy. At the time of Harkavy's 1933 report, Sulzberger (17) gave confirmatory results from vaccination of patients with thrombo-angiitis obliterans. He found that in 95 cases of a hospital population including both male and female smokers, but excluding thrombo-angiitis obliterations patients and non-smokers, 36 % gave positive skin reactions to tobacco. Fifty-eight non-smokers were positive in only 16% of the cases. In 1934, Sulzberger (18), using denicotinized extracts and a solution of 0.4% nicotine, obtained, with ten nicotinless extracts, positive wheals in 78% of a series of thrombo-angiitis obliterans patients and in 36% of 95 controls. The nicotine injections Sulzbreger finds surprisingly inactive and innocuous. A group of cases reacting with wheal formation was investigated for passive transference and found all negative but one. Therefore, he concludes that the sensitization found is non-atopic and without re-agins. Sulzberger believes that an organ or part of an organ may be sensitized and that all allergens have favorite foci of sensitization. His test of sensitization is the production of the urticarial wheal.

In a previous communication (19), the authors reported the results of a study of sensitivity to intradermal injection of tobacco extract in a series of patients affected with peptic ulcer.

Two extracts of tobacco were used, one supplied by Dr. Coca and one prepared by Coca's method, of a combination of many tobaccos obtained at a tobacco shop. Fifty-five ambulatory patients with roentgen diagnoses of peptic ulcer were tested with Coca extract diluted 1:10 and with the extract of the combination of tobaccos, without dilution and diluted 1:10. Two of these patients gave characteristic positive reactions to the three preparations. Passive transfer was negative in each case.

After the completion of the above work it was pointed out that this method was faulty in that the extract had not been used in concentrated forms as in Sulzberger's study of thromboangitis obliterans. Ac-

*From the Sub-Clinic of Gastro-enterology, Third Medical Division, Bellevieww Hospital, New York City. (The New York University and College of Medicine).

Submitted January 27, 1936.

cordingly a new series of patients has been studied with the use of a concentrated extract.

METHOD

A tuberculin syringe was used to inject 0.02 c.c. of the concentrated extract intracutaneously into the outer aspect of the arm. This was followed immediately by a similar amount of diluting fluid near the first injection, as a control. The patient was kept under observation for one hour. The greatest reaction during that period was recorded.

Reactions were considered positive only if the following three conditions were found: (1) the wheal must be larger than the control wheal; (2) it must be surrounded by a definite zone of erythema; (3) it must show unmistakable pseudopod formation. In positive cases, passive transference by the method of Prausnitz (20) and Küstner was done. Control injection was made in the other arm in these cases.

MATERIAL STUDIED

Forty-four male patients with roentgen diagnoses of peptic ulcer, all smokers of tobacco were given these supplementary tests with concentrated tobacco extract.

RESULTS

Four of the forty-four patients gave marked characteristic positive reactions to the concentrated extract. Passive transfer was attempted from each of the four cases to four different individuals. Such was negative in the sixteen instances.

SUMMARY AND CONCLUSIONS

A former report is quoted where fifty-five peptic ulcer patients given intradermal injections of tobacco protein gave no evidence of sensitivity to tobacco protein. A criticism of this work is noted, namely that one of the two tobacco preparations was only used in dilution 1:10 and not in concentrated form. Forty-four more similar patients are reported, injected with the concentrated extract. Four of these gave positive local reactions. In every instance passive transfer was negative.

It is concluded from these combined results that it cannot be proved that sensitivity to tobacco protein plays any part in the pathogenesis of peptic ulcer since in no case was it possible to demonstrate re-agins and in neither series were wheals obtained in any significant proportions.

Mesenteric Thrombosis

By

SAMUEL S. BERGER, M.D., F.A.C.P.*

and

ROBERT R. BLONDIS, M.D.

CLEVELAND, OHIO

WE deem it worth while to call attention to this small series of cases of mesenteric thrombosis because, contrary to our former conception of the condition, the diagnosis is easily made if it is borne in mind.

The most common combination of pre-existing findings were advanced age, marked arteriosclerosis, auricular fibrillation and left ventricular failure. When an individual with these manifestations suddenly develops abdominal pain, which at first is intermittent in character and which may be localized anywhere in the abdomen and shows no tendency to subside, one should consider mesenteric thrombosis. If, in addition, stool is passed and contains blood the diagnosis practically is complete. If the bowel is not evacuated spontaneously, and one is considering the possibility of a mesenteric thrombosis, it is well to look into the bowel and see if there is bloody stool present and not wait for a spontaneous evacuation. Practically all of the instances of mesenteric thrombosis were accom-

*Chief and Resident, respectively, of the Medical Department, Mt. Sinai Hospital, Cleveland, Ohio.

Submitted January 27, 1936.

panied by varying degrees of shock, fall in blood pressure and leucocytosis.

The literature on this subject which is in the English language for the last ten years is sparse; many of the cases reported were not proved by autopsy. In our four cases which were substantiated by autopsy, the diagnosis of probable mesenteric thrombosis had been made when the patients were first seen by us. Two of the cases, however, refused operation, one was *in extremis* and an operation could not be undertaken, one patient was operated upon and an extensive resection of the small bowel was performed.

CASE REPORTS

Case 1. Patient was a 69 year old, white female who complained of generalized abdominal pain which had started three days prior to hospital admission The patient had been known to have hypertension for many years. During her present illness, the abdominal pain was accompanied by nausea, vomiting and constipation On the

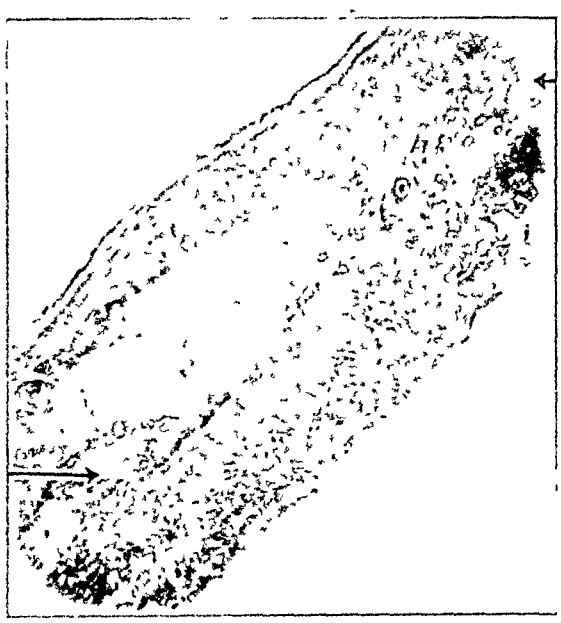

Fig. 1. Early gangrene (small intestine). Section of small bowel exhibiting infarction (Case 1).

day of admission, the patient had three bowel movements, each containing gross blood.

The *physical examination* revealed a dehydrated, senile female in shock. A slight amount of nodular thyroid tissue was palpable. Moist rales could be heard over both lung bases. The auricles were fibrillating at a rapid rate. The abdomen was rigid, tender mostly on the right side with evidence of peritoneal irritation. A *diagnosis* of probable mesenteric thrombosis was made. Operation was refused. The progress was rapidly downhill and the patient expired shortly after admission.

The *necropsy* revealed mesenteric thrombosis with infarction of the jejunum and ileum (Fig. 1).

Case 2. Patient was a 70 year old, white male, complaining of pain in the umbilical region. He had been under care for arteriosclerotic cardio-vascular disease for eight years and gave a history suggestive of a previous cerebral thrombosis He also had symptoms referable to vascular disease of the extremities.

Twenty-four hours prior to admission the patient experienced a cramp-like pain in the umbilical region; this was accompanied by shortness of breath and a feeling of weakness. He became markedly nauseated but did not

Fig. 2 Thrombosis of the superior mesenteric artery. (Case 2).

vomit. The pain migrated to the right lower abdominal quadrant No stool could be obtained.

Physical examination revealed a poorly nourished, white, elderly male He was in a state of severe shock There were many moist rales at both lung bases. A pleuropericardial friction rub was heard over the apex of the heart The abdomen was markedly distended and tender The tenderness was most severe in the epigastrium and lower quadrants. There was generalized abdominal muscle spasm The patient vomited large quantities of dark brown fluid

A diagnosis of probable mesenteric thrombosis was made but the patient's condition precluded operative intervention. He expired The autopsy revealed thrombosis of the superior mesenteric artery with infarction and gangrene of the small bowel (Fig 2).

Fig. 3. Thrombosis of the mesenteric artery. (Case 3).

TABLE I

Summary of Clinical and Laboratory Observations in Four Instances of Mesenteric Thrombosis

	CASE I	CASE II	CASE III	CASE IV
Age	69 years	70 years	76 years	76 years
Duration of complaint on admission	72 hours	24 hours	72 hours	Developed while in the hospital
Previous thrombosis or embolism elsewhere	None	Probable thrombosis. Cerebral artery 5 years previously	None	None
Manifestations of previous cardiovascular damage	Hypertension Auricular fibrillation	Dyspnea for 8 years. Transient numbness left side of body and left extremities 5 years ago — alternate pallor and cyanosis of toes	Thyroid adenoma	Hypertension; Auricular fibrillation
Outstanding features of present illness	Generalized abdominal pain —nausea — pain became more severe. No B.M. for 3 days. On day of admission had 3 B.M. without catharsis	Cramping pain in umbilical region—dyspnea, weakness—sudden nausea and vomiting —pain concentrated in right lower quadrant and became worse	Pain radiating across lower abdomen — distension — constipation—nausea and vomiting — Pain increased in severity. Bloody stool obtained by enema; lethargy	Sudden, lancinating pain in lower abdomen accompanied by nausea, vomiting and passage of bloody stool
Appearance	Emaciated — irrational. Actually ill — complains of severe pain—in shock	Poorly nourished — Acutely ill — in shock — vomited large quantities of dark brown bloody fluid	Undernourished — semi-stuporous—in shock after surgery —stupor deepened into coma and shock increased	Poorly nourished—in shock—slight dyspnea
Presence of heart failure	Left ventricular failure	Left ventricular failure	Left ventricular failure	Left ventricular failure
Condition of blood vessels	Marked peripheral sclerosis —Dorsalis pedis arteries not palpable. Varicosities of lower extremities	Large vessels were sclerotic and tortuous—Dorsalis pedis arteries not palpable—varices of lower extremities	Marked sclerosis of peripheral vessels—dorsalis pedis arteries not palpable	Marked sclerosis of peripheral vessels—dorsalis pedis arteries not palpable
Findings by examination of the abdomen	Generalized spasm — rigidity on right side—tenderness and rebound tenderness	Markedly distended with diffuse tenderness most in epigastrium and lower quadrants—marked muscle spasm	Distended — marked muscle spasm most severe in umbilical region	Rigid — distended — diffusely tender but most severe in lower abdomen
Blood in stool Constipation or diarrhea Duration of condition when first seen	Yes Constipated 65 hours	Blood looked for but no stool obtained Constipated 11 hours	Yes Constipated 36 hours	Yes Constipated 6 hours
Result	Expired	Expired	Expired after laparotomy	Expired after laparotomy
Laboratory findings	Urine— Albumin + loaded with W.B.C. occasional cast Blood— W.B.C. 23,500 R.B.C. 4,250,000 Hgb. 70% T Chem—N.P.N.—40	Urine— Albumin + Casts + W.B.C. + R.B.C.+ Blood— R.B.C. 6,500,000, W.B.C. 20,350, Hgb. 90% S. Chemistry—normal	X-ray abdomen; air distended loops of bowel arranged in layers Urine— Albumin + W.B.C. — occasional Blood— W.B.C.—20,000	Urine— Albumin + W.B.C. — Blood count—record lost
Autopsy findings	Mesenteric thrombosis—Infarction of jejunum and ileum — Chronic cholecystitis — Cholelithiasis — Chronic appendicitis and peri-appendicitis — Serosanguinous peritonitis	Arterial and arterioler sclerosis Myomalacia of heart — Adhesive pericarditis — Mural thrombosis of left ventricle — Thrombosis of superior mesenteric artery with infarction and gangrene of small bowel — Hemoperitoneum — Embolism left iliac artery — Bilateral renal infarcts — Encephalomalacia—Passive congestion of both lung bases	No autopsy but findings at operation as follows: Sero —sanguinous peritonitis — gangrene of jejunum and part of ileum thrombosis of superior mesenteric artery	Considerable athero — sclerosis —ulceration and thrombosis of upper part of thoracic aorta — rheumatic scars in myocardium—old infarct in kidneys — thrombosis of mesenteric artery — acute gastritis—central necrosis of liver — paralytic jejunum — pulmonary edema — adenomatous goitre — chronic cholecystitis with stones—infarction of small bowel
Blood pressure	130/90	100/80	90/60	100/50 after operation 30/0?
Pulse	144 (apex) 120 (radial) aricular fibrillation	120	Auricular fibrillation	120 (auricular fibrillation)
Temperature (rectal)	99° F.—rising steadily to 105° F.	99°-101° F.	99° F.	99°—100° F.

Case 3. Patient, a 76 year old, white, female, was under the care of Dr. L. J. Markus. She had experienced lancinating pains across the lower abdomen for about 72 hours before she was seen in consultation by one of us (S.S.B.). The patient had had a subtotal thyroidectomy 25 years previously for thyroid toxicosis.

The present illness was initiated with abdominal pains and later constipation. Nausea and vomiting appeared soon after the onset. The pain increased in severity and became localized to the umbilical region where it remained. Stool obtained by enema was grossly bloody.

Physical examination revealed an undernourished white senile female in shock. A small thyroid adenoma was palpable. There were a few moist rales over the right lung base. The auricles were fibrillating at a rapid rate. The abdomen was distended and rigid. Direct and rebound tenderness was most marked in the umbilical area.

A diagnosis of probable mesenteric thrombosis was made. The patient was immediately operated upon under local anesthesia and part of the jejunum and the entire ileum which showed infarction were removed; a jejunostomy was performed. The patient did not rally from the shock but expired a few hours later. The operation also revealed a serosanguinous peritonitis, gangrene of a part of the jejunum and the ileum and thrombosis of the superior mesenteric artery (Fig. 3).

Case 4. Patient was a white male, aged 76, complaining of generalized pain in the abdomen. He was under care for arteriosclerotic cardio-vascular disease.

The present illness developed while the patient was in the hospital for an unrelated condition. He suddenly experienced lancinating pain in the lower abdomen accompanied by nausea, vomiting and the passage of bloody stools.

Physical examination revealed a senile, white male in shock. A few moist rales were audible over both lung bases. The abdomen was rigid, distended and diffusely tender.

A diagnosis of mesenteric thrombosis was made and immediate operation was advised. The patient, however,

refused surgical intervention. He became rapidly worse and expired in a few hours.

Autopsy revealed thrombosis of the mesenteric artery and a paralytic jejunum.

SUMMARY

These four proven cases of mesenteric thrombosis exhibited almost identical major manifestations.

In most instances of this acute complication of advanced arteriosclerosis the diagnosis or at least the suspected diagnosis of this condition can be made when the patient is first seen if the condition is borne in mind.

In this series of four cases the diagnosis was made at the first contact but unfortunately the condition had been present in one patient for 6 hours, in another 11 hours, another 65 hours and another for 70 hours. All of the patients were in shock.

Heretofore, as cases generally are recorded in the literature also undue delay has occurred between the time the diagnosis was made and the surgical intervention. In spite of the advanced age of these patients, early diagnosis and early surgical intervention may be life-saving.

The ultimate *prognosis* of acute mesenteric thrombosis practically is hopeless. The underlying factors themselves fundamentally are serious, and the added shock of the thrombosis combined with surgical intervention make the prognosis graver. Yet because of the ease of diagnosis of the condition, if such is promptly made and followed by immediate surgery, an occasional life may be saved.

Treatment of Peptic Ulcer by Means of Injections*

By

C. A. FLOOD, M.D.

and

C. R. MULLINS, M.D.

NEW YORK, NEW YORK

THE relief of pain in peptic ulcer by means of daily injections of histidine monohydrochloride has been reported by numerous workers in the past two years. The claim is made that the pain usually disappears after several injections while the patients remain ambulatory and eat a normal diet. In evaluating the benefits of this method of therapy, control observations using some inert substance such as salt solution or distilled water usually have not been made. Such control studies are of particular importance because of the psychic factors in ulcer and also because of the tendency to spontaneous remissions in the disease.

The use of histidine in peptic ulcer originates from the observations of Weiss and Aron in 1933. They reported that it protected dogs against the formation of jejunal ulcer after the Exalto-Mann-Williamson operation. We have recently repeated this experimental work and also obtained some evidence of protection against ulcer with histidine. Weiss and Aron also studied the effect of histidine injections upon patients with active peptic ulcers and found that symptoms usually disappeared within a few days after the onset of injection therapy. This has been confirmed by Blum, Bulmer, Volini, Eads and others.

AUTHORS' WORK

The object of the present study was to compare a series of patients treated with histidine injections with a control group injected with normal saline. Eighteen ambulatory patients with active duodenal ulcer were used. The diagnosis was confirmed in all cases by X-ray examination. Ten of the patients had been treated in this clinic for previous attacks of ulcer and were considered to be "stubborn cases." All patients except one had been having daily epigastric pain immediately before the onset of injection treatment. None of the group had had a recent gross hemorrhage and none had pyloric obstruction as measured by the presence of a gastric residue six hours after a barium motor meal.

Twelve patients in the group were given daily intragluteal injections of 5 c.c. of normal saline solution. The other six patients received 5 c.c. of a 4 per cent solution of histidine monohydrochloride ("Larostidin," Roche) in a similar manner. The number of patients treated with histidine was limited to six inasmuch as many workers have definitely shown that the administration of this substance is usually followed by relief of pain. All of the injections were given by the writers and at the outset the patients were assured that relief of symptoms was to be expected.

The type of diet both before and during treatment is shown in the accompanying Chart. It will be seen that most of the patients were on a regular diet during the period of injection.

Because the patients were seen every day for treatment, it was feasible to keep a record of their daily symptoms. These were tabulated according to the custom of the Surgical Follow-up Clinic of the Presbyterian Hospital, a numerical value being given as a

*From the Departments of Medicine and Surgery, College of Physicians and Surgeons, Columbia University, and the Presbyterian Hospital, New York City.

Submitted April 23, 1936.

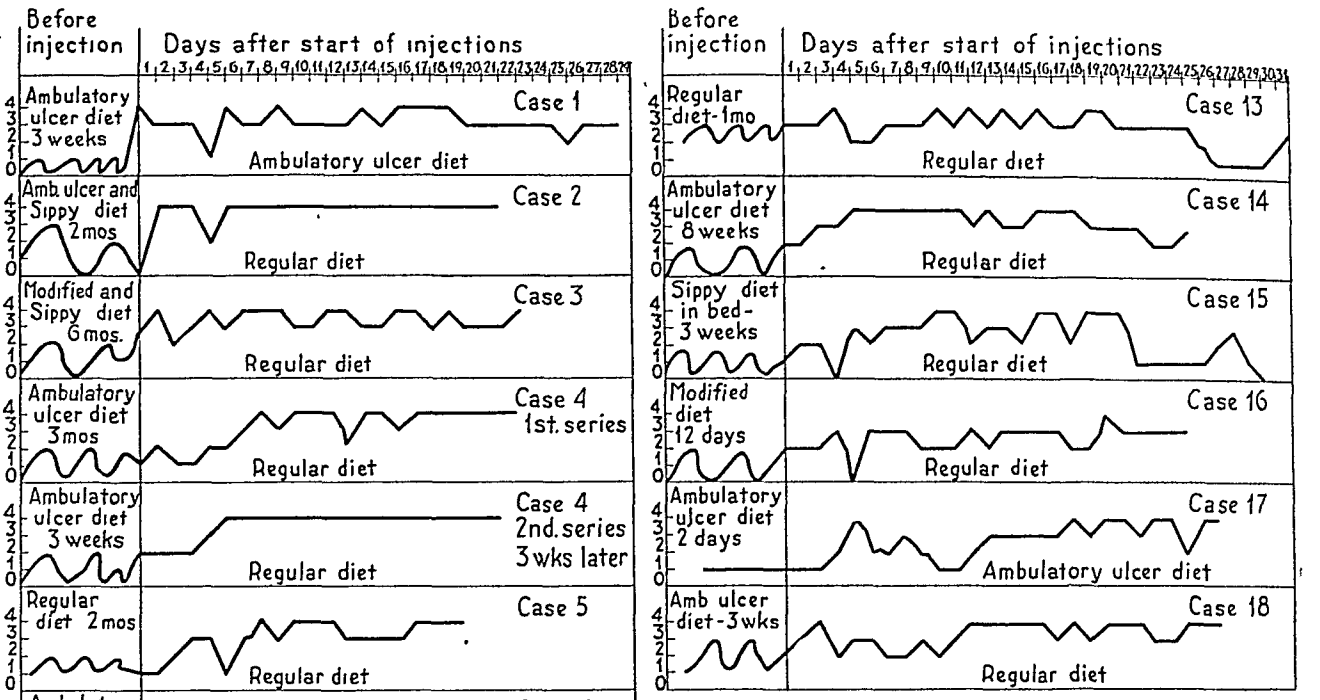

Chart I. Effect of injection treatment upon the symptoms in duodenal ulcer. Cases 1-12 received daily injections of saline. Cases 13-18 received daily injections of histidine monohydrochloride. The method of graphing the severity of symptoms is described in the text. Each graph represents the duration of the attack before injection treatment and the diet before and during treatment.

measure of the severity of symptoms during the previous 24 hours, as follows:

4 — symptom-free
3 — symptom-free except for slight "gas" or heartburn
2 — moderate epigastric distress
1 — severe pain, e.g., pain waking the patient at night; vomiting
0 — incapacitating symptoms

RESULTS

Eight of the 12 patients who received daily saline injections experienced complete relief of pain during treatment. This was in all cases very prompt and after three or four injections, the pain usually vanished. In one patient the pain disappeared as soon as injection treatment was suggested. Several individuals stated that they were able to eat foods which they had been unable to tolerate for a long time and testified that they had not felt so well in many years. The other four members of this group continued to have pain during the treatment.

Of the six patients who received histidine, four became symptom-free except for occasional "gas" during treatment. The other two subjects became definitely worse. One was a patient who was given the drug prophylactically. At the onset of treatment he was almost symptom-free but toward the end of the series of injections he developed symptoms of a recurrence of the ulcer.

All cases have been observed for one to four months since the course of injections was completed. Of the 12 cases who received saline, five remained well and seven had recurrent pain. The latter seven patients were subsequently placed upon frequent feedings, with alkalies and six of them experienced improvement. One (Case No. 4) continued to have severe pain. Upon this patient's request, a second series of saline injections was given and the pain again disappeared. After completion of the second course, the pain returned once more, and the patient requested a third series of injections.

Three of the six patients who received histidine remained well; one had a recurrence of pain relieved by diet, and two continued to have symptoms in spite of subsequent dietary therapy. One of the latter two

patients was hospitalized and subsequently died of hemorrhage from the ulcer.

COMMENT

The fact that daily injections of saline relieve pain in a substantial proportion of patients with peptic ulcer suggests that the therapeutic value of the various types of injection therapy for ulcer lies at least partly in the ceremony of giving the injection. Sandweiss has currently found that daily injections of distilled water relieved the symptoms in peptic ulcer in about one-half of his cases. These findings also emphasize the susceptibility of the patient with ulcer to the suggestions of the physician. It is our general impression that any new treatment for ulcer is successful in the majority of patients until the novelty has worn off. Furthermore, many people who are not improving with one form of treatment respond promptly to a change in therapy whatever that change may be. For these reasons it is not surprising that the daily injection of inert substances relieve the symptoms in peptic ulcer.

SUMMARY

1. Daily injection of saline for a period of about three weeks was attended by relief of pain in eight of 12 patients suffering from active duodenal ulcer.

2. Daily injection of histidine monohydrochloride (Larostidin, Roche) was followed by relief of pain in four of six patients with duodenal ulcer.

3. It is suggested that the successful results in this type of therapy in peptic ulcer are due to the psychotherapeutic value of the injections rather than the nature of the solution used.

4. Relief of pain in peptic ulcer by injection of salt solution emphasizes the importance of the psychic factor in the disease.

5. The evaluation of any therapy for pain in peptic ulcer should be controlled by comparison with the effect of inert substances administered in the same way.

Note: The histidine monohydrochloride (Larostidin, Roche) used in this study was supplied by Hoffman-La Roche, Inc.

An Epidemic of Bacillary Dysentery in the Elgin State Hospital*

A Preliminary Report

By

LOUIS H. BLOCK, M.D.

and

ABRAHAM SIMON, M.D.

ELGIN, ILLINOIS

DIARRHEA occurring in a patient or a group of patients confined in an institution should be immediately investigated, the cause determined, treatment instituted, and necessary measures taken to prevent the spread of the disease if it happens to be infectious. The tendency to regard this complaint rather nonchalantly is fraught with considerable danger and may lead to serious consequences.

Bacillary dysentery is no more a disease limited to the tropics or the southern states. It is decidedly on the increase in temperate climes. Sporadic as well as endemic and epidemic types are being encountered with greater frequency and unfortunately are unrecognized until, in many instances, the autopsy table is reached.

INCIDENCE

Bacillary dysentery epidemics occur in institutions, camps, prisons and asylums. It was known as "asylum dysentery" because of the frequency with which it broke out in these places until it was proved to be bacillary dysentery by Duval and Bassett. Joseph Felsen, Emilie V. Rundlett, James Sullivan and Harold Gorenberg reported an outbreak of a typical Flexner dysentery in Jersey City in July, 1934, with a mortality of 2% in severe cases. L. L. Stanley, F. E. Garfinkle and W. P. Goddard reported an epidemic of Flexner dysentery occurring August 3, 1929, in the San Quentin Prison in which 946 inmates were afflicted and no mortality attributed to this disease. The duration of this epidemic was approximately two weeks. Felsen and A. G. Osofsky have just completed an epidemiologic study of an outbreak of Sonnè dysentery (closely related to the Flexner type) which occurred at the Bronx Hospital, N. Y., the latter part of December, 1933, and January, 1934. This outbreak occurred in midwinter and was traced to a child who had an interval appendectomy performed. Soon after discharge, a number of cases, only in children, although this organism may attack adults too, occurred in quick succession lasting twelve to twenty-four hours but unaccompanied by physical disability.

Epidemics occurring in the mountainous regions of Virginia have been reported by Higgins and also by

*From the Proctologic Department and the Laboratories, the Elgin State Hospital.
Submitted February 12, 1936.

Higgins and Silverman who show that this disease is on the increase in this state and other southern states. They assert that it will spread gradually throughout the United States unless steps are taken to check it.

The significance of this warning can be appreciated when one is cognizant of the increasing number of dysentery cases seen everywhere. This paper will be limited to a preliminary report of a severe epidemic of bacillary dysentery occurring at the Elgin state hospital. (This attack was confined almost entirely to the adult population and two young children who were exposed remained unscathed).

THE ELGIN EPIDEMIC

On June 18, 1935, a patient, Miss R. L., age 27 years, located in the Hirsch cottage (an "untidy" cottage of the institution) was seized with severe abdominal cramps, nausea, frequent and bloody diarrhea, prostration and high temperature (104° F. per rectum). She was transferred to the hospital for treatment and discharged July 9, 1935, with a diagnosis of non-specific enteritis. August 6, 1935, there was a recurrence of symptoms and she returned to the hospital for three days and was discharged. She remained in the cottage for seven days and August 16, 1935, returned once more to the hospital for treatment, this time being discharged in three days as cured.

There were no other cases observed until the 24th of June (7 days after the first case was reported) when two cases appeared: one in the same cottage (Hirsch) and another one in a male infirmary. These two cases remained in their respective wards for treatment. June 28, 1935, one more case appeared in the female infirmary. Then on July 2, 1935, thirty-five cases suddenly developed in Hirsch cottage—exactly fourteen days after the onset of symptoms in the first patient in this ward — and the epidemic began to spread throughout the institution in *bizarre* fashion until 475 patients and an undetermined number of employees, nurses, physicians and members of their families were affilicted. Of this number 357 were females and 118 were males. (See chart). The U. S. Veteran section of the institution remained singularly free of any involvement in this outbreak.

AGE INCIDENCE: The ages and number of patients are given in Table I.

TABLE I

Morbidity and Mortality

Age	No. of Cases	Deaths	Percentage
14-29	83	2	2.4
30-39	83	6	7.2
40-49	102	13	12.7
50-59	83	14	16.9
60-69	77	20	26.0
70-79	38	11	29 0
80-86	9	3	33.3

ETIOLOGY

Our experience in the determination of the etiological factor has been unlike many of those reported in the past. At the beginning of the severe outbreak in July, a few specimens of stools were submitted to the State Department of Public Health for examination and found to be negative for bacillary or amebic dysentery. Repeated cultures of stools made in the laboratories of the hospital showed B. coli only in pure culture and the epidemic was regarded as a non-specific type of entero-colitis. On August 8, 1935, the stools of two patients were reported positive for Hiss dysenteriae by the State Department of Public Health. August 9, 1935, ten blood specimens were submitted for agglutination tests and all but two were negative to Shiga and Flexner. Two agglutinated Flexner in very low dilutions; 1:80 and 1:40 and were regarded as negative. August 23, 1935, (9 weeks after onset), we began to proctoscope every new case and some old cases and took specimens directly from the base of the ulcers, if present, or the mucus from the mucosa and sent the swabs to the Department of Public Health for cultural studies. Up to December 15, 1935, we received only eight positive reports for Shigella parady-senteriae, variety Flexner. These same eight individuals had positive agglutination tests for Flexner. Three agglutinated in dilutions of 1:80; four in dilutions of 1:160, and one in dilutions of 1:320. All other specimens of blood submitted were entirely negative. In the course of this investigation we discovered one

Fig. 1. Shows sacculation and perforation of weakened wall of caecum caused by extensive ulceration and necrosis. Large ragged ulcers of variable sizes and with undermined edges and necrotic bases may be seen throughout this specimen. The intervening mucosa is intensively hyperemic and oedematous and assumes a polypoid appearance. This marked degree of involvement was pronounced in the caecum and ascending colon and gradually decreased in intensity in the distal portion of the large bowel, so, that only a moderate hyperemia and few superficial ulcers were noted in the rectum and sigmoid. The small bowel was only slightly hyperemic and not ulcerated. This patient was positive culturally and serologically.

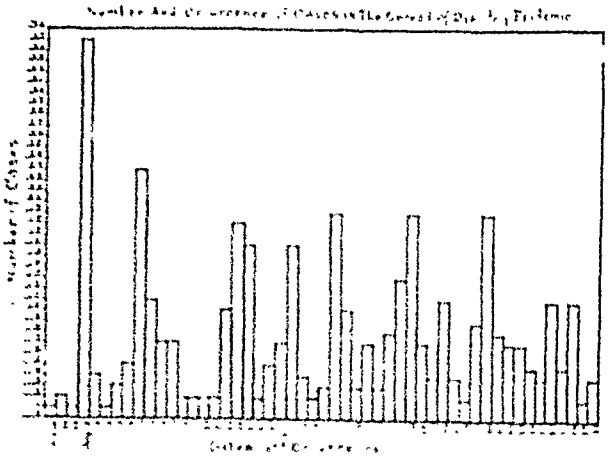

Chart Ia

food handler who was a typhoid carrier. These were the only positive bacteriologic and serologic findings determined from an aggregate of 488 proctoscopic and fifty-five blood specimens examined. Direct smears, the hanging drop, and cultural studies were made to exclude amebiasis, ulcerative colitis and typhoid.

The onset and course of the disease, proctoscopic appearance of the lesions and the bacteriologic and serologic findings seem to justify our conclusion that the epidemic was caused by the Shigella paradysenteriae, Flexner variety.

EPIDEMIOLOGY

Bacillary dysentery is usually conveyed to individuals through the ingestion of water, milk or food contaminated by carriers. Excreta of active cases are extremely contagious and the most scrupulous care in washing hands, and in some cases, the body, is necessary to prevent the spread of this disease to epidemic proportions.

The origin of this Elgin epidemic is still a matter of uncertainty. Investigators from the State Department of Public Health made a survey, recommended cultures of water and milk, and offered certain suggestions relative to changes in the water and milk supply and food containers.

In addition we made a complete and thorough survey of the 214 patients and 46 employee food handlers who were working at the beginning of the outbreak. All of these individuals were proctoscoped and all suspicious cases were immediately dismissed from food handling duties.

The disease is definitely not water-borne because the Veteran group which had the same water supply but not the same milk or food supply was not affected.

It might have been milk-borne. The morning milk supply for the entire institution, except the Veteran section, is furnished by cows on the hospital farm and is not pasteurized. Specimens of milk examined at the time showed an excessively high bacterial count but no dysentery. The afternoon and evening supply is furnished by city dairies. In a survey of all food handlers we found one patient with an active case of dysentery who worked around the cow barn. He made no complaint at any time and did not appear ill. He refused at first to submit to an examination and only after much persuasion finally consented, when we were amazed to find that the entire bowel up to 18 cms. was hyperemic, and ulcerated and some of the mucosa, distally appeared granular and pitted as a result of recently healed ulcers. Scrapings from the base of the ulcers were positive for Shigella paradysenteriae, Flexner variety, and his blood agglutinated Flexner in dilutions of 1:160. Another patient who has been a milker was found to have a hyperemia of the bowel. He denied having had diarrhea. These two patients were immediately isolated. The latter returned to work in the dairy after two subsequent cultures proved to be negative.

Upon investigation we found some individuals who did not drink milk but had been afflicted with dysentery. However, this does not entirely exclude this source as a possibility because, we are sure, cream was consumed by these individuals.

Rosenau states that there is no record of a milk-borne outbreak attributable to properly pasteurized milk.

Contaminated food as a likely source is very probable. Our attention was directed to the fact that on the farm colony no case of dysentery was noticed until two days after their kitchen was closed and food was received from the general kitchen serving the rest of the institution. In the examination of food handlers fifteen patients and three female employee food handlers were temporarily dismissed because of suspicion of being carriers. One of the employees (female) who worked in the physicians' dining room was found to have a positive culture for Shigella paradysenteriae, Flexner variety, and her blood serum agglutinated Flexner 1:160. She was isolated until three successive cultures were negative and has now been assigned to some work in the laundry. All the others returned to work as soon as their cultures were found to be negative on three successive examinations.

All the buildings were properly screened, but it was impossible to keep flies from entering the various kitchens and dining rooms because doors were kept open for long periods of time to permit patients and employees to enter and leave. Many flies were also

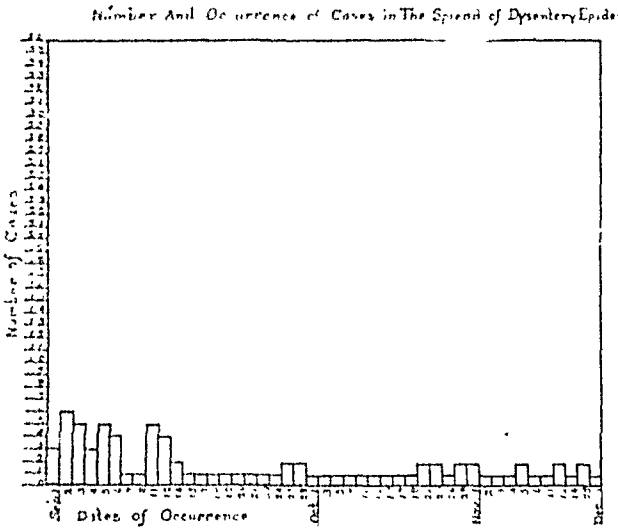

Chart Ib

carried in by patients. It is quite possible that flies may have contributed to the spread of the disease.

BACTERIOLOGY

Excepting the fecal cultural work which was performed before one of us (L.H.B.) arrived at the institution, all of the specimens submitted for cultural studies to our laboratory and to the laboratories of the State Department of Public Health were taken through the proctoscope directly from the base of ulcers or from the mucus deposit on the wall of the bowel, and some plated immediately on Endo medium. A total of 260 plates were thus inoculated and carefully cultured and worked up by the State Department of Public Health. In addition 228 swabs were handled in a like manner. Of this number only eight were found to be positive for dysentery—amounting to less than ½ of 1%, an infinitely small showing for an epidemic of this size.

Unfortunately this intensive work was not started until two months after the beginning of the outbreak and for this reason probably did not yield good results. Nevertheless, there were 117 acute cases observed during this period and still the number of positive bacteriologic results was not increased, probably due to delay in incubating the inoculated media. Our bacteriological experience has amply proved that these organisms are difficult to isolate even when using the direct method of obtaining specimens, but that repeated cultural studies should be made in all suspicious diarrhea cases, preferably securing specimens through a proctoscope.

SYMPTOMATOLOGY

Period of Incubation: The exact period is difficult to determine. Seven days elapsed before other cases appeared after the first one was reported. Following this the period of incubation was much shorter. The prevailing opinion is that the incubation period is between one and seven days.

Mode of Onset: The onset varied so much in intensity that we can conveniently divide it into three types.

Symptomless Type: A few cases were accidentally discovered in the course of our survey who denied having had diarrhea or any other symptoms of dysentery. In one case, a dish washer in one of the kitchens had a profuse diarrhea at the time of examination and subsequent proctoscopic examination revealed a hyperemic bowel. His temperature was normal, he did not complain of any abdominal cramps and felt perfectly well. His cultures and serological examinations were negative. In another instance described above the patient made no complaints whatsoever referable to the gastro-intestinal tract, was afebrile and did not appear ill. He was positive proctoscopically, culturally and serologically for Shigella paradysenteriae, Flexner variety.

It would be futile to venture a guess as to the probable number of symptomless cases in the institution unless every patient were thoroughly examined—an almost impossible feat. However, we are sure there were many cases of this type which were overlooked because the symptoms were so mild in character and the mental condition such that the patient was not cognizant of it, or too indifferent to complain.

Mild Type: The preponderance of cases noted, amounting to 289, were mild in character with temperatures ranging from normal to 101°. (Duration was from one to four days). They did not appear very ill and had little tendency to tenesmus and bloody diarrhea. These cases, usually young individuals, were treated in the ward in which they happened to occur.

Severe Type: There were 186 recorded cases of this type occurring in the most debilitated individuals, in the higher range of ages. The symptoms appeared suddenly, ushered in with marked prostration, pyrexia of 101° which rapidly rose to 106°, and in two cases to 107.6°, nausea and vomiting, and severe tenesmus and excruciating pain over the entire abdomen, particularly in the right lower quadrant. Diarrhea was extremely frequent, and the stools contained variable amounts of blood from a good sized hemorrhage to streaking, mucus, mucopurulent material and no fecal matter. The patient suffered a great deal from an incessant and annoying desire to evacuate the bowels. The number of stools was large, often reaching to 30 or 40 a day, and the quantity evacuated was very small.

As the disease progressed the character of the stool changed and often pseudomembranous casts were passed. The stool was extremely offensive, had a characteristic odor much like that of semen and was no longer watery but serous and dark from altered hemoglobin. Vesicle tenesmus characterized by marked discomfort and frequency of urination was a troublesome symptom. The mouth was dry and the tongue swollen and heavily coated. As a result of the excessive loss of fluid from the body the patient complained bitterly of thirst.

The disease, usually self-limited, ran a course of from 10 days to two weeks. Some cases became subacute and ran a course of a month or more, and a few became chronic. A number of patients became extremely toxic and death ensued within the first few days and in some cases in a few weeks.

Chronic Type: We still have under our care six chronic cases who have periods of remission. They are markedly emaciated, afebrile, and have frequent stools: dark, serous, bloody and offensive. There have been times when their stools were formed and they had one or two evacuations daily but this period of improvement was of short duration.

DIAGNOSIS

The diagnosis of this disease would have been readily made if the cultural and serological tests were all positive. Often it is impossible to isolate the causative organism and one must rely, if dealing with an epidemic type of dysentery, on many other factors. The clinical history was strikingly similar in every case. In addition other findings contributed to the support of the diagnosis of bacillary dysentery.

Physical examination in the mild type revealed very little that was significant except some tenderness over the caecum and sigmoid regions on deep pressure. However, in the severe cases the patient appeared acutely ill, very pale, ran a high temperature, had a rigid and sometimes distended abdomen which was very tender to palpation, particularly over the large colon. There was no involvement of the liver or spleen.

Proctoscopic study of all cases is unquestionably indispensable in the determination of the nature of the diseased condition with which we are dealing. A total of 595 proctoscopic examinations were made (by L.H.B.) in the course of our work. The patient, if cooperative and not too ill, was placed in the knee

shoulder position. If this was impossible, he was placed over the side of the bed or table with the head resting on a pillow placed on a low chair or floor. A well lubricated index finger was introduced slowly and gently to determine the condition of the sphincter, anus, and lower rectal ampulla. (Invariably in dysentery, especially if severe, the sphincter was markedly spastic). This was followed by the introduction of the proctoscope. Not unmindful of the fact that in bacillary dysentery the passage of the proctoscope is painful (a diagnostic point of interest) much care was taken to make the procedure tolerable. In most instances we were successful in reaching the recto-sigmoid junction without causing unnecessary discomfort.

The appearance of the proctoscoped field in acute cases was characteristic. The mucous membrane was intensely inflamed, in many cases oedematous and actually caused a narrowing of the lumen of the bowel. Slightest trauma produced a bleeding surface which was sometimes profuse. There were numerous superficial ulcers covered with a pseudodiptheritic membrane usually seen on the crests of the folds of the mucous membrane running transversely to the lumen of the bowel. These ulcers were irregular, jagged, and not undermined. As these small discrete ulcers began to spread and coalesce until they formed large irregular confluent patches the folds of the mucous membrane seemed to disappear. The intact mucous membrane, intensely inflamed, presented peculiarly geographical areas which often became polypoid in character. In some cases the process of necrosis was so extensive that large sheets of this necrotic tissue could be seen in the lumen of the bowel.

Most of the patients were observed from time to time so that many received from two to three or more proctoscopic examinations. As the ulcers gradually disappeared and the oedema and hyperemia subsided, the mucosa assumed a granular appearance and many small dimpled areas could be seen, caused by the healed ulcers. Healing begins at the distal end of the rectum (usually the muco-cutaneous junction) and gradually continues upward to the other portions of the colon. We observed no strictures directly attributable to this disease in this series of cases.

COMPLICATIONS

Only one case of arthritis was noted which occurred in an employee a few weeks after onset of mild symptoms. However, she gave a history of a previous attack of arthritis about seventeen years ago. Four patients developed peritonitis due either to the extension of the inflammation to the serous layers of the bowel or to perforation. In one case, a chronic type, a perforation of the caecum was found on autopsy.

TREATMENT

This consisted of rest in bed, limited liquid followed by high caloric, non residue diet, belladonnae, bismuth subcarbonate, and occasionally an opiate. Irrigations with pot. permanganate were given to hospital cases. In severe toxemia intravenous saline and glucose was given as indicated.

We resorted to the use of serum in a limited number of cases. Serum acts in two ways: neutralizes the toxins liberated by the infecting bacilli, and destroys the bacilli themselves. A large quantity of the serum is necessary to combat the effect of the absorption of toxins due to its low antitoxic content, and should be given intravenously early in the disease. Polyvalent, Shiga and Flexner, dysentery serum (Lederle) in 50 c.c. doses, mixed with 50 c.c. of normal saline, was administered intravenously to nine patients. In all cases there was an elevation of temperature from 100° to 105°. Two cases expired in a few days; one case received 100 c.c. and later on another 100 c.c. of convalescent serum and finally expired. An employee, 50 years of age, severely ill, who received the serum within twenty-four hours after onset of symptoms, experienced relief of abdominal pain, cessation of tenesmus and frequent bowel movements; and within five days all symptoms disappeared and the extensive lesions of the bowel wall almost entirely healed. He recovered completely in seven days. Of the remaining six patients, three recovered entirely and three became chronic.

At this time Dr. Read suggested the use of convalescent serum and through the courtesy of the Michael Reese Serum Center a supply was prepared for our use. 250 c.c. of blood was drawn from each of twenty-eight convalescent patients and twelve vials containing 100 c.c. each of mixed serum was prepared. We administered 600 c.c. to five different patients. There were no reactions following its use, no elevation of temperature, and apparently no change in the condition of the patients.

Sodium thiocyanate as suggested by Mitchell and Goldman was administered to some of the patients, acute and chronic types, but without appreciable effect. This result corroborated the findings of the authors that this preparation was useless except in B. Shiga dysentery.

FATALITY

There were sixty-nine deaths—forty-five females and twenty-four males—making a gross fatality rate of about 16.5%. This would doubtless be much lower were we to include the indeterminate number of unrecognized patients in our calculations.

Sex apparently does not influence the rate. Female death rate was about 8% compared to the male of 6%,

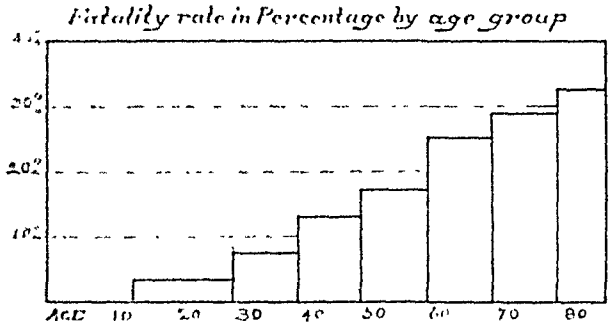

Chart II

the difference probably due to the fact that there were twice as many females afflicted.

Age influenced the fatality rate considerably as shown in Chart II. The sharp increase in fatality with the age of the patient is strikingly pictured.

PATHOLOGY

The disease process is usually limited to the large colon and in very severe cases may mildly affect the mucosa of the small bowel as far as the pylorus. The

caecum, the various flexures, hepatic, splenic, and sigmoidal and the rectal ampulla are greatly affected. The disease usually begins at the most proximal end, the caecum, and gradually spreads to the rectal ampulla. The mucosa and submucosa are intensely inflamed, oedematous, and dark red in color and covered with ulcers. These superficial, shallow ulcers, discreet or confluent, are irregular, jagged, and not undermined, and are covered with a pseudo-diphtheritic membrane which is easily removable. The folds of the mucosa may become thickened and assume a polypoid or cystic appearance. In far advanced cases the muscularis and serosa are involved and, due to the extension of the necrotic process, the wall of the bowel becomes weakened and perforation may ensue or gangrene may develop.

SUMMARY AND CONCLUSIONS

1. Every case of diarrhea occurring in an institution merits a relentless investigation due to increasing incidence of dysentery in temperate climes.

2. An epidemic of dysentery continuing over a period of more than five months, atypical in character, occurred throughout the Elgin State Hospital with the exception of the veteran section.

3. In a population of 4,500 there were 475 patients and an undetermined number of physicians, nurses, employees, and members of their families afflicted.

4. The causative agent was the Shigella paradysenteriae, Flexner variety.

5. The primary source has not been definitely determined. Carriers have been discovered who could have easily polluted both the milk and food supply. However, part of the milk supply is not pasteurized which makes this a potent source for the spread of any infection and particularly bacillary dysentery.

6. A total of 488 endo plates were inoculated and cultured with specimens taken directly from the base of ulcers through a proctoscope and only ½ of 1% were positive.

7. The usual course of the disease varied from four days to two weeks, except in few chronic cases.

8. An intensive proctoscopic study was made of all cases, including food handlers, totalling 595 examinations. This afforded an unusual opportunity to view the various changes that took place in the rectum and bowel during the course of the disease.

9. Limited experience with the use of polyvalent serum has demonstrated its value if administered early and in sufficiently large doses. Convalescent serum prepared for our use has had no effect.

10. Mortality was 14.5% and affected debilitated patients in the higher range of ages.

ACKNOWLEDGEMENTS

We wish to express our appreciation and our indebtedness to H. E. McDaniels and V. M. Ryan, bacteriologists of the Illinois Department of Public Health Chicago Laboratories, for their excellent work in the bacteriological and serological study of these cases; to Drs. S. O. Levinson and A. A. Platt of the Michael Reese Serum Center for the preparation of the convalescent serum; to Dr. Chas. F. Read for his invaluable aid and suggestions, and to members of his staff for securing necessary data.

The Peptic Ulcer Syndrome in the Negro*

Clinical and Statistical Evidence on Psychogenic as Against Racial Factors in the Etiology of this Syndrome

By

FREDERICK STEIGMANN, M.D.†

CHICAGO, ILLINOIS

FROM the enormous literature‡ dealing with the etiology and pathogenesis of peptic ulcer it is apparent that more than one cause is active in the genesis of peptic ulcer. The majority of clinicians today hold that certain of these causes can be grouped under the so-called "systemic factors" (30). These are taken to include a great number of psycho-physiologic processes and peculiarities that affect man alone, such as physical characteristics (9, 30, 31, 33), constitutional factors (13, 34, 38), certain diatheses (13), familial tendency (1, 20, 29), sex (30, 31), general health and resistance (30), mental and nervous reactions (1, 3, 4, 10, 19), emotions (1, 5, 10, 33), moods (18, 25), and tendency to perseverance (1, 30). Occasionally they include even personal achievements (30) based on intensive study or work, and the complexities of modern American life, characterized by stress, strain and speed. In other words, certain selective features of anthropometry, personality, sex, and environment which seem to be playing an important role

Submitted March 2, 1936.

‡In 1931 Cushing stated that the references on peptic ulcer etiology and pathogenesis, the number of which was listed by Moeller as 325 in 1911, had probably quadrupled by that time. In 1936, therefore, the number is surely much higher. Hence the references listed for this paper were, with few exceptions, strictly those dealing with the neurogenic or psychogenic phase.

in the genesis of peptic ulcer are discussed under the heading of systemic factors.

Although some authors speak of a "peptic ulcer race" (9) in a certain etymological sense, the racial factor in an ethnological sense, has been rarely considered and then only superficially. In fact, racial selectivity has been mentioned only by one writer (31) while another (30) has called attention to the rather rare occurrence of peptic ulcer in the colored as compared with the white race. Thus Rivers (25) reports the surprising fact that of two hundred Negroes interviewed in a certain county in Texas only three per cent gave a history of indigestion, and only one individual gave symptoms suggestive of peptic ulcer. This appeared the more significant to him because those Negroes had lived on a non-balanced diet, dissipated recklessly, used tobacco and alcohol excessively, lived under poor hygienic conditions, were without work, and scarcely knew the source of their next day's food. Racial selectivity, as a factor *per se* has been stressed by Robinson (31) who states "the Negro and lesser pigmented races are immune to the disease (peptic ulcer); the white race alone is susceptible. The pure blooded Negro is practically immune to the disease because of hereditary differences of psychological structure and function. The Negro race in its evolutionary ascent has not as yet acquired the habit of worry so peculiar to the white race under pressure of routine civilized living."

AUTHOR'S STUDY

The present study is an outgrowth of the discrepancy between the above quoted statement and the observations made by this writer in the course of his work at the Cook County Hospital in Chicago. If the Negro is "practically racially immune to peptic ulcer," then peptic ulcer in the colored race should be extremely rare. If, on the other hand, peptic ulcer is rare in the Negro in the agricultural areas of the South and common in the Negro in the industrial areas of the North, then the Southern Negroes are protected from peptic ulcer by special factors other than race.

The first fact that became apparent to the writer was that the Negro patients with peptic ulcer whom he interviewed were vastly different individuals from the indifferent types of Texas Negroes described by Rivers (30). Although on the whole somewhat less apprehensive and less complaining than white ulcer patients, they nevertheless were far from being indifferent. They worried about their health, lack of economic security,* their diet, and other things too numerous to mention. In short, these Negroes lived under the same conditions of stress and strain as the whites, and reacted to them in substantially the same way.

In order to check the discrepancy between these observations and the conclusions reached by Robinson (31), the writer proceeded to gather statistical evidence. In the course of 1934, 67,831 patients were admitted to the Cook County Hospital (including readmittances). Of this number, 604, or 0.88 per cent were diagnosed peptic ulcer clinically and roentgenologically. Seventy-seven, or 12.7 per cent of these were Negroes. Ninety-seven, or 16 per cent, of the 604 ulcer cases were patients admitted with perforated peptic ulcer, and of these, eleven, or 11.3 per cent were colored. In the gastro-intestinal clinic, of 605 active cases (*i.e.* reporting to the clinic at least once in six months), ninety-seven, or 16 per cent, are Negroes: eight, or 8.2 per cent of them having had operations for perforated peptic ulcer.

It was further noticed that in these colored patients the average duration of symptoms referable to the gastro-intestinal tract was about five years, while the average time they had been in Chicago was about eleven years. The relation of the average time lived in Chicago to the average duration of ulcer symptoms

*See Footnote at end of this contribution.

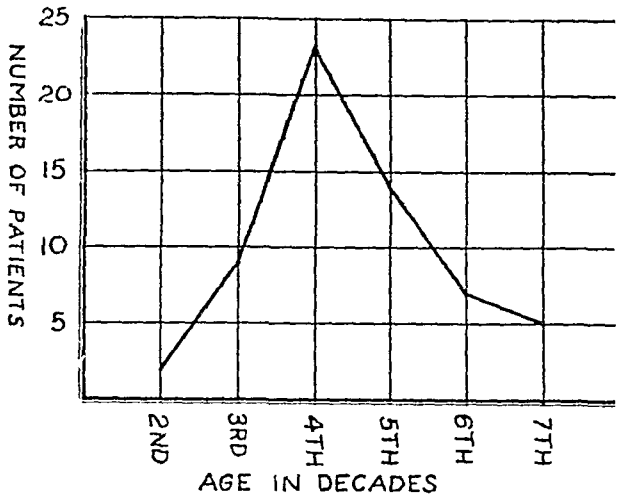

FIG. 1 THE DISTRIBUTION OF PEPTIC ULCER IN DIFFERENT AGE GROUPS

is quite striking in this ratio. It should be noticed that these patients lived in this environment for some time before the symptoms of peptic ulcer appeared. Furthermore, individual figures are even more impressive, as they give definite evidence that the symptoms referable to the gastro-intestinal tract appeared often many years after their arrival in this region. Indeed, only in three patients was there a history of gastro-intestinal disturbance dating back to their residence in the South.

In order to check further the validity of these statistics, data were gathered relative to Negro ulcer patients and Negro admittances from other hospitals in Chicago and elsewhere. Thus it was found that of all patients admitted to the Cook County Hospital within a period of one month (considered conclusive for our purpose), 27.7 per cent were Negroes. Returns on questionaires received from other free hospitals are given in Table I.

It is obvious from these data that the Cook County Hospital is not unique in having a fair proportion of colored peptic ulcer patients.

Sixty colored patients reporting regularly to the gastro-intestinal clinic were chosen at random and interviewed in regard to their age, habits of smoking and drinking, diet, living conditions, number of dependents, schooling, and economic adjustment. These patients had also their blood pressure and degree of gastric acidity determined. The results obtained are given below in graphic form.

These graphs clearly show that (1) the condition is most common between the third and fourth decade, when responsibilities are usually greatest; (2) habits were essentially moderate, forty-five being habitual smokers and only two indulging in alcohol beverages; (3) diet was fair on the whole, although none of them complained of poor food; (4) living conditions were tolerable; (5) nearly two-thirds of them had two or more dependents; (6) only nine had no schooling, but the remainder had from four to eight years of grammer school, ten of these having attended high school and three even college; (7) only twelve were employed, twelve of them being unemployed because of poor health; (8) most of them had a systolic blood pressure range of 120 to 140, and a diastolic range of 70 to 90; and (9) the majority of patients had a free acidity above thirty degrees, several of them having free acid values in excess of seventy degrees, but three had an achlorhydria (*i.e.* with one Ewald meal).

The results of the analysis of these social-economic factors clearly manifest the bases for a number of psychic stimuli to which these patients were exposed. The worry, fear, anxiety, and other emotional tensions present in these individuals were probably of sufficient strength to affect the neuro-vegetative center and thus to produce, through their autonomic outflow, derangements in the function of the gastro-intestinal tract (15), which ultimately led to subjective and objective symptoms characteristic of peptic ulcer. This does not imply that mental impulses mediated by the neuro-vegetative center in the diencephalon are the sole cause of peptic ulcer formation, but it does mean that these impulses are of paramount importance, and that locally acting stimuli are only supplemental in nature. It also suggests that these psychogenic-neurogenic impulses act as the exciting factor (32) of a peptic ulcer syndrome, and that without them the local component is symptomless. This would explain why a recurrence of peptic ulcer symptoms is experienced more often after some upset in the psychic, rather than in the somatic component (38, 1, 3, 10, 28, 37). It would also tend to explain why Negroes in industrial centers are more likely to have peptic ulcer symptoms even though the local stimuli (diet, etc.), are, if anything, less severe in the urban (Northern) than rural (Southern) Negro. Finally, it shows why the results of peptic ulcer treatment are much better and recurrences rarer in clinics, where the patients are from smaller communities than in the clinics which treat predominantly city dwellers (33). The only reason for this difference is that in the latter clinics the patients are individuals who are under the influence of psychic stimuli to which the patients of the first clinics are either not exposed at all, or are exposed only to a small degree.

DISCUSSION

The pros and cons (11, 12, 16) of the systemic factors in the genesis of peptic ulcer have been discussed by a large number of clinicians, some of them

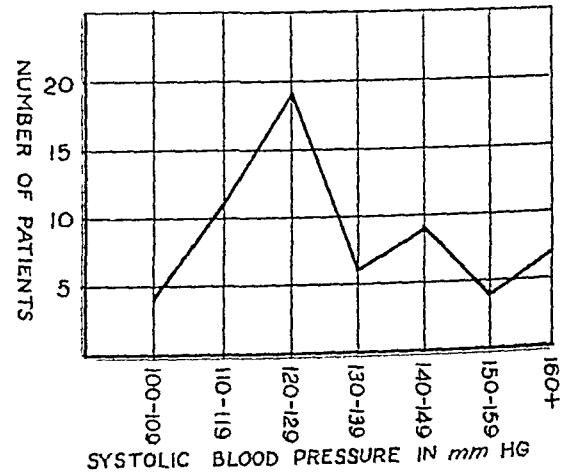

FIG. 2 SYSTOLIC BLOOD PRESSURE IN PEPTIC ULCER PATIENTS

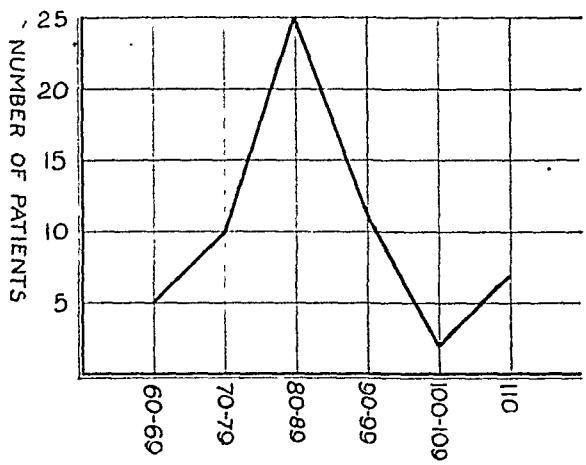

FIG. 3 DIASTOLIC BLOOD PRESSURES OF PEPTIC ULCER PATIENTS

outstanding figures in the medical world, yet none of them has referred to racial selectivity as playing an important, or in fact any, role whatsoever. Only recently, Moschcovitz (27) in listing several syndromes, among them gastric and duodenal ulcer, which he believes to be psychogenic, stated "that such diseases are but exaggerations of normal function; they are essentially human diseases and cannot be produced experimentally in animals; they rarely occur before the emotive and affective powers are fully developed; their life cycle is characterized by a great tendency to recurrence; their incidence bears a strong relation to world crises or great emotional waves" but failed to mention that they occur only in the white race. It would, therefore, seem strange indeed that all these men should have overlooked such an important factor, if it actually exists. Even if the continental writers are eliminated from this group of clinicians, as their material is based on white patients almost entirely, there still remains a considerable number of American authors whose material consisted of mixed races (Whites and Negroes). When such comprehensive reviews on the subject as have been written by Cushing (8), Alvarez (1), Smithies (35), Crile (6, 7), and others fail even to suggest a racial selectivity factor, its existence becomes quite doubtful. If, moreover, various observations and statistics show that peptic ulcer is found in a comparatively high percentage of Negroes in different geographical areas, then the theory of racial selectivity in the genesis of peptic ulcer becomes untenable.

In referring to racial selectivity as a unique feature of peptic ulcer, Robinson (31) states that the colored race is "skipped by the disease" because of hereditary differences in psychological structure and function; and that in its evolutionary ascent it has not acquired as yet the habit of worry so peculiar to the White race under pressure of routine civilized living. From this assertion it is inferred that the Negro belongs to a more primitive race, and has by heredity a different psychologic structure and function. The question thus arises, first, whether this assertion is correct and peptic ulcer is found less frequently in the Negroes because of their race and inherent psychological structure and function, or, secondly, whether this statement is incorrect and the lesser incidence of peptic ulcer in the Negroes is due to the environment which has protected most of them from the effect of harmful psychogenic influences. The first question must be answered in the negative. The second question is best answered in the affirmative.

The subject of racial differences has recently been covered by Klineberg (23) in his *Race Differences*. After an exhaustive survey of the voluminous literature on this subject the author summarizes the present day attitude of psychologists, based on objective findings. He concludes that the characteristics that distinguish human races are morphological, and that physiological, psychological and even pathological differences remain to be proved (*p. 18*). He disposes of the fallacious assumption that one race is more primitive than another *(p. 36)*, and goes on to say that we have no right to regard every Negro as differing from every White, or to expect that all Negroes will behave similarly in similar situations (*p. 20*). He establishes definitely the immense influence of environmental, social, and economic factors on the results of intelligence tests, on which the presumptuous notions of racial differences are based. The importance of these factors is most clearly apparent from the results of intelligence tests given to similar groups of Negroes in different geographic areas showing that the Negroes in the North, Northeast, and Northwest are much superior to those in the South (*p. 183*). The importance of the environment is supported by similar conclusions reached by Lorimer and Osborne (24), (*p. 198*) who state "Among large regional groups in the United States differences in economic and other environmental factors, such as climate, education, and so forth may be sufficient to explain cultural-intellectual differences without recourse to genetic explanation."

Since, however, not only intelligence but personality also has been used to differentiate the races, Klineberg (23) analyzes the findings of a number of authors who tried to prove or disprove these conceptions, and concludes that objective measurements of "non-intellectual" traits also failed to demonstrate racial differences (*p. 207*), and that hence *culture* appears to determine situations that arouse emotional responses, to regulate the extent to which these responses are overtly expressed, and the particular forms which their expression may take (*p. 287*). His final conclusion is that the case for psychological race differences

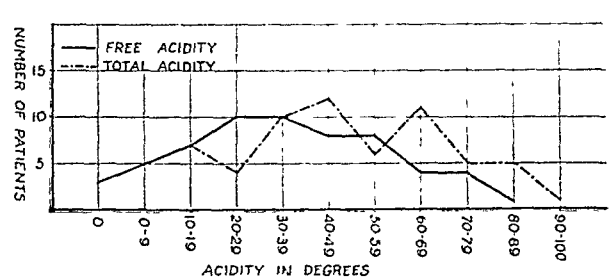

FIG 4 DISTRIBUTION OF PATIENTS ON THE VARIOUS LEVELS OF FREE AND TOTAL ACIDITY

has never been proved and that there is no scientific evidence of racial differences in mentality (*p. 345*).

From the statistical data offered and the various critical comments on the role of systemic factors in the genesis of peptic ulcer, nothing seems to point to a racial selectivity. Moreover, from the conclusions cited in regard to psychological differences between races, a racial selectivity based on differences of psychological structure and function appears to be scientifically intolerable. It is manifest that the role of environmental stimuli on the vegetative nervous system in the production of peptic ulcers in Negroes (as in Whites) has been substantiated by the conclusions of various writers. If the differences in emotional response are not to be explained on the basis of innate racial make-up, but on the basis of *culture* (the latter being used to mean attitudes and experiences which an individual receives from the society of which he is a member), then it stands to reason that the Negro in the North will respond to emotions (overt or repressed) and other stimuli to the vegetative nervous center in the same manner as do other members of the society to which he belongs, society here including both Whites and Negroes. Similarly, the Southern Negro will less frequently be beset by peptic ulcer, as the White members of his society are also affected but little by this syndrome as compared to their Northern brethren.

In closing, it may thus be stated that the clinical and experimental observations of a large number of investigators, and the study of our own clinical material, justify the following conclusions: First, that peptic ulcer is not due to any one specific cause—selectivity or unique feature—but to a combination of a variable number of factors which have been best described by Rivers (30). Secondly, that although hyperchlorhydria is not a prime requisite for peptic ulcer (36), most peptic ulcer patients, nevertheless, show hyperchlorhydria, hypersecretion, hypermotility, and hypertonicity (17, 37). The last is especially marked in the pyloric portion, and is the precursor of pyloric spasm which is believed to play an important role in the genesis of peptic ulcer (21). Thirdly, that all these gastric phenomena can be produced by the stimulation of the neuro-vegetative center in the diencephalon, a center which is easily affected by psychic influences (8, 14, 22, 26). Fourthly, that on the basis of these observations it may be assumed that digestive disturbances, hyperacidity, and even ulcer, will occur in vagotonic individuals who, according to Cushing (8) are under the domination of such psychic stimuli as overt or repressed emotions, incidental or continued worry, anxiety, heavy responsibilities, etc., alone, or in combination with locally acting factors, such as improper food, excessive food and drink, etc. Finally, that these vagotonic individuals do not belong exclusively to the white race, but may also be members of the colored race, a fact which explains why peptic ulcer is not as rare in the Negro as the theory of racial selectivity would lead one to believe. This is of importance clinically in that it suggests that the clinician must approach the problem of peptic ulcer in the Negro with the same attitude as he does in the White patient.

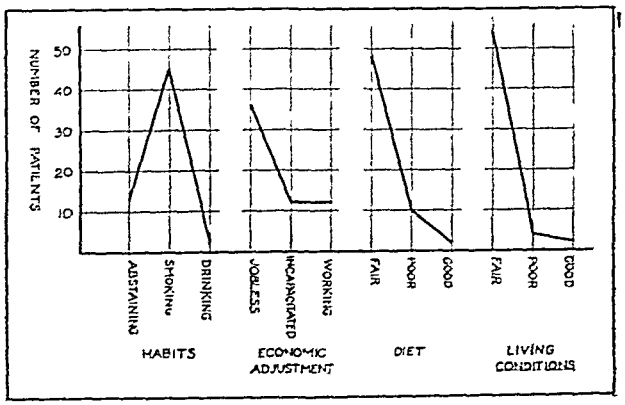

FIG. 5 PATIENTS' HABITS IN REGARD TO SMOKING AND DRINKING, ECONOMIC ADJUSTMENT, DIETARY REGIMEN, AND TYPES OF DOMESTIC SURROUNDINGS

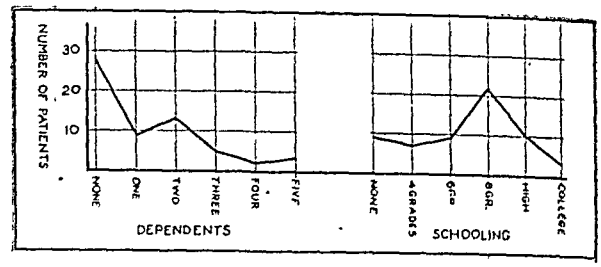

FIG 6 PATIENTS' RESPONSIBILITIES AND EDUCATION AS INDICATED BY NUMBER OF DEPENDENTS AND YEARS OF ATTENDANCE AT SCHOOL

SUMMARY

1. Negroes constituted 12.7 per cent of all the peptic ulcer patients admitted to the Cook County Hospital during the period of one year, while slightly higher or lower percentages are found in other hospitals admitting both White and Negro patients.

2. Environmentally conditioned psychic factors play an equally important role in the genesis of peptic ulcer in White and Negro patients.

3. Northern Negroes, hence, of industrial centers, just as the Whites of these areas, are more frequently subject to peptic ulcer than Southern Negroes and Whites of agricultural areas, respectively.

4. The theory of racial selectivity as a unique feature of the peptic ulcer syndrome could not be substantiated, while the hypothesis on which this theory of racial selectivity is based is contrary to the latest conceptions of comparative psychology.

I wish to express my sincerest gratitude to Dr. M. H. Krout and Dr. H. A. Singer for their helpful suggestions during the preparation of this paper.

Footnote: In the phrase "worry about lack of economic security" we included a number of things which seemed to worry these patients, particularly as gathered during the interviews with them. Some of the more outstanding things that worried the greater number of these individuals are given below: insecure jobs; disagreeable work; small pay; insufficient money for rent, gas and electricity with the associated fear of eviction and shutting off the gas or electricity; lack of carfare to go about; lack of money for personal spending; small relief allowances; friction with the case worker and landlord; separation of family members due to breaking up of home; improper clothing for public appearance; insufficient clothes for themselves and the children; irregularity of school attendance by their children, because of lack of certain parts of the clothing; lack of opportunities for their children; loss of property and fear of losing certain possessions, etc.

The Differentiation of Surgical and Medical Groups of Jaundice*

By

ARTHUR A. HOLBROOK, M.D.†

MILWAUKEE, WISCONSIN

WHEN confronted by a patient with jaundice, the inevitable question arises: Is surgical relief of obstruction indicated? If the answer is to be affirmative, it is desirable to establish the fact as early as possible so that preoperative measures can be properly carried out and the risks attending prolonged intoxication, obviated. This paper deals with only those procedures alleged to be most useful in differentiating the jaundice due to infectious, toxic hepatitis (medical) and that of common duct obstruction (surgical).

In studying these problems there is no laboratory test or combination of tests which can take the place of a careful history, physical examination, and routine observations of chart, blood counts and smears, urines and stools. Lahey's (1) modification of Courvoisier's law is worth alluding to in this respect: "In the presence of jaundice which is painless and progressive and associated with consistently acholic stools, a dilated gall bladder palpable through the abdominal wall is almost certain to be due to malignancy of the head of the pancreas or the lower end of the common duct." Thus simply by the use of sight and touch it is possible to decide the diagnosis. The cataloging of significant points in the histories of 235 cases of jaundice by Flood (2), Seegal, *et al* has shown that revision is needed in the commonly accepted teaching that cancer of the head of the pancreas causes painless jaundice. They found a high incidence of pain as the earliest symptom. Scrutiny of ten times as many cases might supply ten additional important facts to serve clinical judgment. Even then, however, certain decisions could be facilitated by special laboratory evidence.

LABORATORY AIDS

There are five laboratory procedures which have been especially stressed in the literature as having distinct value in the differential diagnosis of intrahepatic jaundice and extrahepatic (obstructive) jaundice: the qualitative van den Bergh reaction, the galactose tolerance test, the urobilinogen determination, the duodenal tube drainage and the study of blood choles-

*From the Division of Medicine, Milwaukee County Hospital.
†Clinical Instructor in Medicine, Marquette University School of Medicine.

Submitted March 4, 1936.

terol. I do not discuss flat X-ray plate of the gall bladder region, because by showing a stone, that examination can simply refine the diagnosis of obstruction.

(1) *The Qualitative van den Bergh Reaction:* The history of this test has been summarized by Rabinowitch (3); the technic, by Elton (4). The bio-chemical mechanism involved has not yet been established. In interpreting the test according to van den Bergh and McNee, a direct immediate reaction means obstructive jaundice; a biphasic reaction denotes the jaundice of hepatitis; and a delayed reaction means hemolytic jaundice.

In 1930 Snider and Reinhold (5) felt there was no valid theoretical basis for the use of the van den Bergh reaction in identifying the various types of jaundice. The next year Rabinowitch (3) wrote that the different reactions did not yield the information attributed to them and offered the explanation that pure obstruction and pure hepatitis are rare. Cantarow (6) observed that the varying responses of the test at different times in the same individual tended to discredit its value in differential diagnosis. Some use was accorded the test by Flood, Seegal (2), *et al* in differentiating hemolytic from non-hemolytic jaundice; but none, in the differential of obstructive and hepatic jaundice. By and large, present day investigators (7, 8) frown upon the value of the qualitative van den Bergh reaction.

(2) *The Galactose Tolerance Test:* Davies (8) gives an historical account of this test and describes his technic of giving the sugar and following the blood levels. Roe and Schwartzman (9) use a similar technic but vary their doses according to body weight. Jankelson and Lerner (10) give the galactose intravenously, instead of orally, and follow the non-fermentable fraction of the blood sugar curve as an index of galactose utilization. Most workers (Shay and Schloss (11); Banks, Sprague and Snell (12); Schiff and Senior (13); Rosenberg (14)) adhere to the principles first set down by Bauer in 1906.

The value of this test is said (11) to lie in the fact that all the galactose which fails to be utilized by the liver is eliminated in the urine. Thus in the early presence of jaundice if more than 3 grams are recovered, diffuse liver damage is postulated, and a toxic or infectious type of jaundice is thereby identified. On the other hand, excretion of less than 3 grams is normal and an indication that the etiology of early jaundice is either obstruction or hemolysis. Schiff and Senior (13) applied the test in 100 cases and concluded that it was of great value in differentiating acute toxic or infectious jaundice from the obstructive type. Rosenberg (14) obtained normal (negative) results in all his 16 cases of obstructive jaundice and commented favorably on the value of the test. Clute (15) remarks that the test is simply confirmatory but settles nothing. Banks, Sprague and Snell (12) studied 127 selected cases of jaundice including the two groups under discussion here. They concluded that the galactose test does not uniformly distinguish between obstructive and intra-hepatic types of jaundice, though it may furnish valuable corroborative data in doubtful cases. Their records show clear cut examples in which excessive galactose was excreted (positive tests) in obstruction cases of relatively short duration (4 to 14 days). Shay (13)* answered for these unfavorable results by saying that the tests were not done early enough and that some of the cases perhaps had infection in the biliary tract. Rosenberg (14) suggested that Banks *et al* might have made more accurate use of the test by combining it with the urobilinogen test. Davies (8) and Mann (13)* also advocate the employing of various tests to settle a differential diagnosis.

(3) *The Urobilinogen Determination:* Value of the Urobilinogen test in diagnosis was demonstrated about 50 years ago by Friedrick Müller. He observed that no urobilinogen was present in the urine of a patient with complete biliary obstruction. Thereupon he gave large amounts of bile by mouth and within 48 hours obtained positive urinary tests for urobilinogen.

During the next 40 years the test was refined and the mechanism of urobilinogen production was investigated.

Ten years ago (June, 1925) Wallace and Diamond (16) employed the newer knowledge and reported their studies of 1200 cases, thereby giving prominence to the test. They outlined the rationale and technic of the procedure and gave experimental evidence to support their views which have been generally accepted ever since. Briefly, they asserted that urobilinogen is derived from bilirubin in the intestine, is absorbed from the intestine, and is normally excreted mostly by the liver but also in small amounts by the kidneys. If diffuse liver damage is present, the excretion through the biliary channel is impaired and excessive amounts are put out in the urine. If obstruction to the flow of bile into the duodenum is complete, urobilinogen is non-existent. The authors mention two exceptions to the latter statement. First, in the presence of cholangeitis, bilirubin may be reduced in the infected bile ducts to urobilinogen. Second, small amounts of bilirubin may be excreted from the general circulation into the intestines where urobilinogen will then form. Davies (8), Rabinowitch (3), Rosenberg (14), and Clute (15) record experiences with the urobilinogen test similar to those of Wallace and Diamond.

If biliary obstruction is only partial or if regeneration has had time to develop in a diseased liver, then manifestly the urobilinogen test loses significance. In neither instance will it be consistently positive or negative. Attempts have been made to increase the value of the test in the more difficult differential diagnoses by combining it systematically with other tests. Thus, Rabinowitch (3) feels that the urobilinogen test in conjunction with the qualitative van den Bergh gives more exact information. Rosenberg (14) suggests that the combination of the galactose tolerance and the urobilinogen tests is useful, but that of the two used alone the urobilinogen is the more reliable for differential purposes.

(4) *Duodenal Tube Drainage:* The various types of duodenal tube have been described by Twiss (17, 18), who has also given detailed account of their use. Part of the routine examination in the Gall Bladder Clinic at the New York Post Graduate Hospital (18) is the microscopic, chemical, and bacteriological analyses of the bile fractions recovered from the duodenum. Lahey (1) has emphasized the value of these diagnostic measures especially in distinguishing catarrhal jaundice from obstructive jaundice due to gall stones. The presence of mucus and pus in thin bile argues for the former. Whereas cholesterol crystals bespeak stone. Whole blood may mean carcinoma. Clute (15) of the Lahey Clinic considers duodenal drainage for diagnostic purposes "perhaps the most satisfactory and dependable laboratory test for determining the cause of jaundice" and mentions a series of 30 correct diagnoses to a single mistaken one made by this means.

Duodenal drainage has been employed chiefly for establishing the presence of gall stones. In 1928, Piersol, Bockus and Shay (20) were thereby able to make preoperative diagnoses of stone in 47% of their cases. Three years later Bockus, Shay, Willard and Pessel (21) made accurate diagnoses in 83% of their cases. They assert that the combination of cholesterol crystals and calcium bilirubinate crystals is pathognomonic of gall stones. It is apparently as important to study bile in diagnosing hepato-biliary disease as urine in renal-ureteral disease.

(5) *Blood Cholesterol:* In 1927 Davies (8) wrote that the blood cholesterol level is an important aid in the differential diagnosis of jaundice. An amount of 180 mg % or more, he said, points to obstructive jaundice. Epstein (22) has done pioneer work in this direction and gathered

evidence to show that a pronounced reduction in the blood cholesterol level indicates parenchymatous disease of the liver, whereas hypercholesteremia denotes an obstructive lesion. Lehnherr (23) records similar experiences with lipid analyses in studying the causes of jaundice. However, his results seem to differ from Epstein's in certain details to do with the free-cholesterol: ester-cholesterol ratios in obstructive jaundice. Such discrepancies simply mean that this work is in its infancy.

CLINICAL STUDY

Although in recent years there has been no special or organized study made of jaundice at the Milwaukee County General Hospital, still certain jaundiced patients have submitted to a wide variety of laboratory tests for diagnostic and prognostic purposes. I have been particularly interested in studying the records of a group of 50 patients who received among other tests the combination of the qualitative direct van den Bergh and urobilinogen determinations. It has seemed desirable to appraise the value of these casual observations.

AUTHOR'S STUDY

The 50 cases under consideration were arbitrarily divided into 27 medical and 23 surgical on the basis of the site of lesion. Those with primary liver disease were considered medical; and those with extra hepatic biliary conditions, surgical. Tables I and II show the details of this grouping.

As intimated in the first paragraph, the special interest of this study is in tests which may expedite early diagnoses. Hence I have recorded only the first results, which were obtained shortly after admission in nearly every instance. The "duration of jaundice" pertains to the period from onset to the initial tests.

The pertinent results of this survey are summarized in Table III. It is interesting to note that in these two heterogeneous groups the figures run approximately parallel. Hence, it would seem that single urobilinogen or van den Bergh determinations can not be expected to help in differentiating medical from surgical jaundice. Further study will be made on the value of repeated tests.

There are not enough cases of any given type within the groups to judge the merits of these tests in distinguishing certain syndromes. Nevertheless, there are indications that even within narrower limits there is nothing specific about these tests. The similarity between cases 3 and 4 of the portal cirrhosis type is striking. The ages of the patients, the depth and duration of jaundice were approximately the same.

*D.IM. Represents direct immediate.
D.D. Represents direct delayed.

The sex and van den Bergh reaction were identical. Yet one gave a markedly positive urobilinogen reaction; and the other, a flat negative. It has been said that early in catarrhal jaundice the urobilinogen test is most likely to be positive. Cases 20 and 21 were examined one week after the onset. One proved negative; the other, positive. The van den Bergh reactions also differed. Cases 10 and 11 with probable cancer of the head of the pancreas, and cases 18 and 19 with gall bladder disease afford further example of discrepancies in the urobilinogen testing of clinically similar material.

TABLE III

	Surgical	Medical
Total positive urobilinogens	13	16
Total negative urobilinogens	10	11
Per cent positive	56.5%	59.2%
Total van den Berghs done	16	24
Direct immediate	11	19
Delayed direct	4	5
Negative	1	0
Per cent direct immediate	68.7%	79.1%

In conclusion, it appears from the above study that isolated urobilinogen and qualitative direct van den Bergh tests do not with any regularity help distinguish the jaundice of medical origin from that due to a surgical lesion. This statement is made, of course, from a statistical point of view. It is only fair to state in addition that the records show certain individual instances in which the urobilinogen test when repeatedly negative has proved to be of definite value in helping to decide whether or not to operate on a jaundiced patient.

SUMMARY

1. Attention is called to the desirability of making early differential diagnoses between "medical" and "surgical" jaundice.

2. In this respect, the importance of bedside observations is stressed.

3. The five most popular laboratory tests for differential purposes are appraised in varying detail.

4. A series of 50 cases is presented in chart form to show especially the value of single urobilinogen and qualitative direct van den Bergh tests in distinguishing "medical" and "surgical" jaundice.

5. The figures indicate that no significant information can be expected from these laboratory procedures on the basis of single observations only.

I wish to acknowledge the generosity of Dr. Francis D. Murphy, Medical Director of the Milwaukee County General Hospital, who suggested this subject and gave me access to the clinical records.

SECTION II—*Experimental Physiology*

An Improved Gastric Test Meal*

By

CHARLES M. WILHELMJ, M.D.
F. T. O'BRIEN, M.D.
and
FREDERICK C. HILL, M.D.

OMAHA, NEBRASKA

STUDIES on gastric secretion are to a certain extent handicapped and limited because of the lack of a standard test meal. The more commonly used clinical test meals (shredded wheat biscuits, arrow root cookies, bread or toast, with water or weak tea) have frequently been justly criticized because of their very low secretogogue effect which renders them inadequate tests of the acid secreting power of the stomach. This generally recognized failure of the usual test meals has led to the wide spread use of histamine, the alcohol test meal or the meat and water test meal.

Histamine is undoubtedly a powerful stimulant for hydrochloric acid secretion, but recent investigations have shown that its action is to some extent abnormal since it appears to stimulate solely the secretion of hydrochloric acid and not that of pepsin and other organic constituents. We have recently shown (1) that histamine may mask certain regulatory phenomena which are seen when meat extracts are used and have concluded that histamine is either qualitatively or quantitatively different from the naturally occurring secretogogues present in meat. The alcohol test meal is too abnormal to be seriously considered. The use of the meat and water test meal, especially in experimental work, is becoming increasingly popular. From the standpoint of a normal, adequate stimulus for gastric secretion it is undoubtedly highly satisfactory but it presents certain very serious analytical difficulties which render the results of doubtful validity. The presence of a high concentration of powerful buffer substances render accurate titration almost impossible. In addition, the acid and alkali combining power of the meat are undergoing constant alterations during the course of the test, due to digestion and liberation of protein digestion products. The assumption that the titration values obtained during the course of the test meal represent hydrochloric acid secreted by the stomach is, to say the least, highly questionable.

In none of the commonly used test meals is it possible to evaluate the factor of dilution of the gastric secretion by the fluid of the test meal; that is, in a given gastric sample it is not possible to determine what per cent of the sample is fluid originally given

*Departments of Physiology and Experimental Surgery, Creighton University School of Medicine.
Submitted March 10, 1936

with the test meal and what per cent is the fluid of the secretions entering the stomach. Because of this it is impossible to determine the true composition of the gastric secretions. An extreme hypothetical example will illustrate the importance of the factor of dilution of the gastric secretions by fluid of the test meal. Suppose that two subjects are given the same test meal which contains 200 c.c. of fluid and that both subjects secrete exactly the same amount of acid of exactly the same strength during the test period. Suppose however that the gastric sample removed from subject A consists of 100 c.c. of fluid from the test meal plus the secreted hydrochloric acid, while from subject B it consists of 50 c.c. of fluid from the test meal plus the secreted acid. Titration of the gastric samples would lead to the erroneous conclusion that subject A secreted only half as much acid as subject B, whereas in reality the amount of acid secreted was the same, the difference being that in one instance it was diluted by 100 c.c. and in the other by 50 c.c. of fluid from the test meal. Gorham (2) pointed out this fallacy and suggested the use of phenolsulphonphthalein (phenol red) in the test meal in order to correct for dilution of the gastric secretions. In a large series of gastric analyses he illustrated the striking difference that may exist between corrected and uncorrected values. In our previous studies on the regulation of gastric acidity we have used phenol red in the test meal and have shown its great value (1, 3, 4, 5, 6, 7).

From the above considerations it follows that an ideal gastric test meal should have the following qualifications: (1) Its secretogogue effect should be high and act through normal channels so that it will be unnecessary to use histamine or other extraneous stimulants. (2) It should be relatively low in organic material and buffer substances in order to allow accurate titration. (3) It should not undergo marked changes in consistency while in the stomach. (4) It must be possible to use phenol red in order to determine the true composition of the secretions entering the stomach. (5) It must be possible to remove pigments, mucus and other interferring substances which might render the colorimetric determination of the per cent of phenol red inaccurate due to foreign color or turbidity. Phenol red must not be removed with these interferring substances. (6) It must be a liquid meal so that phenol red is not adsorbed by solid particles. (7) It must be possible to standardize the test meal, before use, with regard to its content of titratable acid. (8) The meal should have no acid neutralizing or combining power.

In attempting to develop a test meal having the above qualifications, several substances (milk, whey, Armour's meal extract) were tried but, for various reasons, found unsatisfactory. Armour's meat extract was discarded because of the extreme variability in its secretogogue content. Liebig's meat extract (Lemco brand) was found to be quite constant in secretogogue effect and a two per cent solution was found to exert a marked and maintained stimulation of gastric secretion. Since the secretogogues present in Liebig's extract are a concentrated preparation of those normally occurring in meat, it appears that the stimulating effect can be considered to be quite normal in mode of action.

A study of simple, unmodified aqueous (2 per cent) solutions of Liebig's extract showed that where a high degree of accuracy is desired, they are not satisfactory for the following reasons: (1) When slowly acidified with tenth normal hydrochloric acid a degree of acidity is finally reached at which a heavy flocculent precipitate settles out, further addition of acid redissolves the precipitate. A cursory study of this phenomenon suggested that when the precipitate forms there is an exchange of base with neutralization of some of the hydrochloric acid. (2) Aqueous solutions possess a variable ability to combine with and neutralize hydrochloric acid. (3) Non volatile acids are present. These would not interfere with the usual clinical analysis involving only titration, provided that the meal was titrated before using. They would however interfere with the accurate determination of neutral chloride in the gastric samples, a determination which is often of importance in experimental studies.

Because of the above findings it was necessary to prepare a two per cent solution of Liebig's extract in which these undesirable features were eliminated in the following general manner: First, to remove the material precipitated by acid. Second, to supply sufficient base to care for the non volatile acids. Third, to leave the solution slightly acid with hydrochloric acid so that its acid neutralizing and combining powers would be saturated.

Preparation of Two Liters of Two Per Cent Liebig's Extract Test Meal Containing 15 mgm. of Phenol Red per Liter

(1) 40 grams of Liebig's extract are dissolved in one liter of distilled water. The water may be warmed to facilitate solution but should never approach the boiling point since this may destroy the secretogogue.

(2) Add 30 mgm. of the sodium salt of phenol red.[1]

(3) Add 20 c.c. of 20 per cent sodium carbonate solution. After addition the solution should be definitely alkaline as shown by the red color of the phenol red.

(4) Add slowly with constant stirring one liter of tenth normal hydrochloric acid. After addition the solution should be acid to litmus paper.

(5) Let stand until a heavy flocculent precipitate settles out.

(6) Filter. The first portions to pass through the filter may be turbid and should be returned until the filtrate is crystal clear.

Since the meal keeps well with proper refrigeration, a sufficient quantity for one or two weeks work can be prepared at one time. The taste is pleasant being practically that of beef extract, hence it can be taken by mouth. When titrated as described below, the acidity of various batches of the meal will vary from 11 to 22 c.c. of tenth normal acid per 100 c.c.. If values above 22 c.c. of tenth normal acid are obtained alkali should be added to reduce the acidity to within the above range. This degree of acidity has no influence on acid secretion or duodenal regurgitation (1).

The amount of meal administered will depend upon the length of time that it is desired to follow the acidity curve and the number of samples taken. In experiments on dogs we have administered from 600 c.c. to 900 c.c., depending upon the size of the animal and the emptying time of the stomach. Samples (30

1. We have used the dry, powdered phenol red and dissolved the 30 mgm. in 33 c.c. of N/10 NaOH. The amount of alkali used should be kept constant since it is a factor in determining the final acidity of the meal.

c.c.) were removed every half hour until the stomach emptied which required from 1½ to 2½ hours.

METHODS OF ANALYSIS

The analysis consists of two procedures. (A) Titration of the test meal before use and of the samples removed from the stomach. (B) Determination of the per cent of phenol red in the samples removed from the stomach.

(A) *Titration of the Test Meal and of the Gastric Samples*

In previously reported studies on the regulation of gastric acidity we determined the total chloride, neutral chloride and by difference the acid chloride in the test meal and the gastric samples. While this method is highly accurate it is unnecessarily complicated for clinical use. We attempted to work out a method of titrating the total acid which would be in reasonably good agreement with the acid chloride as determined. When phenolphthalein was used as an indicator it was found that the results were much too high and very irregular. Several other indicators were tried and brom cresol purple was found to give results in satisfactory agreement with the acid chloride determinations.

The method of titration is as follows:

A five c.c. centrifuged sample of gastric contents or an uncentrifuged sample of original test meal is diluted with 75 c.c. of distilled water and placed on top of a water bath for 30 minutes. Six drops of brom cresol purple (0.4 per cent in 95 per cent alcohol) are added. The titration is performed on the steaming sample using twentieth normal sodium hydroxide. The result is expressed as c.c. of tenth normal acid per 100 c.c. of gastric sample or test meal. As the alkali is added the color of the solution first becomes a greenish yellow, next a light purple mixed with reddish brown; as more alkali is added this color at first darkens but finally changes to a rich wine colored purple free from reddish brown. The latter is taken as the end point. With practice the end point is easily recognized. The dilution with water and warming are important aids in reducing the effect of buffer substances and producing a sharp end point.

The titration value thus obtained is for total acid. We have not attempted to determine free and combined acid because of the doubtful character of these values (8, 9) and also because it is believed that sufficient information can be obtained from the total acid figure.

A sample of the test meal should be titrated each time that a test is performed.

(B) *Determination of the Per Cent of Phenol Red in the Gastric Samples*

In this determination a sample of the original test meal is used as the standard.

(1) Five c.c. samples of the original test meal and of each of the gastric samples are placed in 15 c.c. centrifuge tubes. (2) Add 2 c.c. of 20 per cent sodium tungstate to each. Mixing is not necessary. Due to the alkalinity of the sodium tungstate the samples turn a reddish color. (3) Add 2 c.c. of 1.33 normal sulfuric acid[2] and mix by inverting several times. Do not shake. (4) Stopper tubes and allow to stand for from 1 to 1½ hours. A flocculent precipitate settles out usually leaving a clear supernatant fluid. The prolonged period of standing is not always necessary but aids materially in clearing the samples when the dilution is great or large amounts of duodenal secretions are present. (5) Centrifuge at high speed for 10 minutes and decant the supernatant fluid into dry 15 c.c. graduated centrifuge tubes. (6) Reduce the volume in all tubes to 8 c.c. and alkalinize by adding to each 1 c.c. of approximately 20 per cent sodium hydroxide (5 c.c. of saturated sodium hydroxide plus 10 c.c. of water). (7) Mix by inverting several times and centrifuge for 10 minutes. (8) Compare the gastric samples with the sample of the original test meal in a colorimeter and determine the per cent of phenol red present. It is best to set the standard at 5 m.m. and make the comparison on this basis.

Immediately after alkalinization the samples turn a purplish red color different from the true color of alkaline phenol red. This is due to certain substances in the Liebig's extract which react with the excess tungstate, in an alkaline media, to produce a blue color. This color fades rapidly and is also absorbed by the small precipitate thrown down and is gone at the end of the 10 minute centrifuging, leaving the true alkaline phenol red color.

If the dilution of the gastric sample has been very great or large amounts of duodenal contents are present, it frequently happens that the treatment with sodium tungstate and sulfuric acid does not yield a perfectly clear supernatant fluid but a milky one which cannot be cleared by centrifuging. Such samples will clear after addition of the alkali and are suitable for comparison.

When large amounts of bile, especially gall bladder bile are present in the gastric sample, the color after alkalinization is often faintly tinged with yellow instead of being the pure alkaline phenol red color. This color can be almost perfectly matched by adding a small amount of picric acid to the standard. The method is as follows: To about 4 c.c. of standard add 4 to 5 *very* small crystals of picric acid and shake until dissolved. By mixing varying amounts of the picric standard with the untreated standard a yellowish tinge can be produced which matches that of the gastric sample. It has not been necessary to use this measure on many normal dogs but it may often be necessary after gastroenterostomy or Polya types of operations.

When an experiment is continued until complete emptying of the stomach occurs it is usually found that the last samples are too dilute to determine the per cent of phenol red accurately. We have routinely accurately diluted such samples with equal parts of the original test meal and made the determination of the per cent of phenol red on the diluted sample. A simple correction[3] gives the per cent of phenol red in the original undiluted sample. With few exceptions we have diluted all samples beginning at 1½ hours. If one uses a greater amount of phenol red in the test meal in order to have sufficient color for the final sample then it is found that the color is too deep for accurate comparison in the early samples. The dilution method has been found very satisfactory.

Bile. If bile is to be tested for in the gastric samples a Pettenkoffer ring test should be used. The meal does not give false positive reactions.

CALCULATIONS

The general principle of the calculation is as follows: while the test meal is in the stomach various fluid secretions are mixed with it. These secretions dilute the test meal and lower the per cent of phenol red. The decrease in the per cent of phenol red in the samples removed from the stomach shows the cubic centimeters of secretions mixed with each 100 c.c. of the sample. If the fluid which diluted the test meal had been a neutral fluid containing neither acid or alkali, then the acid in the test meal would be lowered by dilution to the same extent as the phenol red, hence the acid would be equal to the amount in the original test meal corrected for dilution (multiplied by the per cent of phenol red in the gastric sample). However, if the fluid which diluted the test meal contained acid, the acid added would be the difference between the acid

2. 35 grams of concentrated sulfuric acid diluted to 500 c.c. with distilled water is sufficiently accurate and can be used without further standardization.

3. The per cent of phenol red in the diluted sample minus 50 x 2 gives the per cent of phenol red in the original undiluted sample.

TABLE I

A series of fractional gastric analyses performed on normal dogs

in the original test meal, (corrected for dilution) and the acid in the gastric sample. If the secretions which diluted the test meal contained no acid (total anacidity) then the acid in the gastric sample would be less than that in the original test meal (corrected for dilution) due to neutralization of some of the acid of the test meal. The details are as follows:[4]

(1) *Cubic Centimeters of tenth normal acid secreted*

The c.c. of tenth normal acid in the original test meal multiplied by the per cent of phenol red in the gastric sample, corrects the original test meal for dilution. If the acidity of the gastric sample is greater than this the difference will represent the c.c. of tenth normal acid secreted by the stomach.

Example:

Test meal contains 12 c.c. of N/10 acid per 100 c.c.

Gastric sample contains 48 c.c. N/10 acid per 100 c.c. and 67 per cent phenol red.

12 x 67 per cent = 8 c.c. (correction of test meal for dilution).

48 — 8 = 40 c.c. N/10 acid secreted by stomach.

In total anacidity the acid in the gastric sample may be less than that in the test meal corrected for dilution. The difference represents the acid of the test meal which was neutralized by the mildly alkaline secretions.

Example:

Test meal contains 12 c.c. of N/10 acid per 100 c.c.

Gastric sample contains 2 c.c. of N/10 acid per 100 c.c. and 80% phenol red.

12 x 80 per cent = 10 c.c. (correction of test meal for dilution).

10 — 2 = 8 c.c. of acid in test meal neutralized.

(2) *The Acid Concentration of the Secretions in the Gastric Sample*

The decrease in the per cent of phenol red in the sample removed from the stomach shows the c.c. of secretion in each 100 c.c. of sample. If the c.c. of extra acid are divided by the c.c. of secretion and multiplied by 100 the result will give the c.c. of N/10 acid per 100 c.c. of secretion.

Example:

Per cent of phenol red in gastric sample = 67, hence 33 c.c. (100 — 67) of secretion entered the stomach and were mixed with each 100 c.c. of the sample.

The c.c. of extra N/10 acid = 40.

40 ÷ 33 = 1.21 x 100 = 121 c.c. of N/10 acid per 100 c.c. of secretion in the sample.

A further calculation which has been found of value in studying the results of a gastric analysis is the division of the total fluid secretions entering the stomach into the *acid fluid* and the *non-acid* fluid.

1. *The Total Fluid (Secretion)* entering the stomach is shown by the decrease in the per cent of phenol red.

2. *The Acid Fluid.* The work of several recent investigators (3, 10, 11, 12, 13, 14, 15, 16, 17, 18) has agreed in

4. In the calculations it is unnecessary to use fractions of cubic centimeters. All figures are rounded off to the nearest whole number.

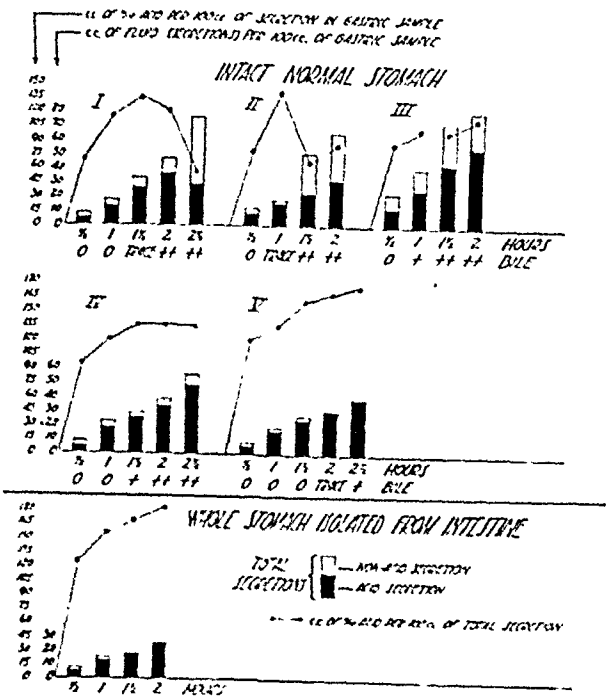

Fig. 1

1. UPPER HALF. The 5 types of Acidity Curves obtained in 67 experiments on 11 normal dogs.
2. LOWER HALF. An average curve constructed from 10 fractional gastric analyses performed on four whole stomach pouches.

showing that the pure acid secretion of the fundic glands is isotonic with the blood and that the strength at which it is secreted remains approximately constant regardless of the rate of secretion and is unaltered by the acidity of the gastric contents. All of the above investigators have obtained approximately the same value for the strength of the pure acid secretion but the most accurate value is that of Hollander (11) who has shown that the pure acid secretion remains constant at 0.170 normal (604 mgm. of acid chloride per 100 c.c.). Because of the constancy of this value it is possible to determine the fluid of the acid secretion. This is done by dividing the c.c. of extra N/10 acid by 1.7.

Example:

The gastric sample is found to contain 40 c.c. of extra N/10 acid per 100 c.c.

40 ÷ 1.7 = 24 c.c. of acid fluid. This value of course represents the acid which was secreted and not neutralized.

3. *The Non-Acid Fluid* is the difference between the *total* and the *acid* fluid. The non acid fluid consists of several secretions in varying amounts and includes, the mucus and mucoid secretions of the pyloric and fundic regions, the regurgitated duodenal secretions and the fluid of acid which was secreted and subsequently neutralized.

The acid concentration of the total fluid entering the stomach is determined by the relative amounts of acid and non acid fluids, the higher the per cent of acid fluid the higher the acid concentration of the total fluid. It is, therefore, often helpful to determine the per cent of acid fluid in the total fluid secretions entering the stomach.

Several complete analyses are shown in Table I.

In the lower half of Figure 1 is shown an average curve constructed from 10 fractional gastric analyses done on four whole stomach pouches. It is seen that the non acid fluid gradually becomes smaller in amount and may finally disappear, hence the acid concentration of the total secretions may reach very high values. This is due to two factors. First the non acid fluid of intragastric origin is small in amount (5) and second, absorption of non acid fluid (water) occurs (19).

In a series of 67 experiments on 11 normal dogs we were able to recognize 5 types of curves which are shown in the upper half of Figure 1. The frequency of these different types was as follows:

Type I	42 or 63 per cent
Type II	12 or 19 per cent
Type III	7 or 10 per cent
Type IV	3 or 4 per cent
Type V	3 or 4 per cent

Types I, II and III comprise 92 per cent of the total number. In these it is seen that there is an abrupt increase in non acid fluid near the end of the curve just before emptying occurs. When these curves are compared with the average curve obtained in the whole stomach isolated from the duodenum, it is evident that the increase in non acid fluid is due to regurgitation of duodenal secretions. Curves of types IV and V are not due solely to lessened duodenal regurgitation but also to absorption of non acid fluid (water) from the gastric contents. A more detafled discussion of these various types of curves has been given elsewhere (19).

SUMMARY

(1) The preparation and use of a new test meal consisting of two per cent Liebig's extract containing phenol red is described. The advantages of this meal over other commonly used test meals are discussed.

(2) Illustrations of the types of curves obtained on normal dogs are given and compared with curves obtained on while stomach pouches isolated from the duodenum. This comparison shows the importance of duodenal regurgitation in determining the type of curve.

Clinical Aspects of Vitamin B-Complex Deficiency in Association with Disease of the Gall Bladder*

Report of an Instance

By

G. LOUIS WELLER, Jr., M.D.

WASHINGTON, D. C

MANIFESTATIONS of deficiency of one or several components of the vitamin B complex are receiving increasing attention particularly from the standpoint of diagnosis. Cowgill (1) has included the far reaching clinical implications of such deficiency in his discussion of vitamin B requirements of man. Elsom (2, 3) notes characteristic symptoms in her two cases of vitamin B deficiency studied clinically. In addition to loss of weight, anorexia, edema, hypotension and signs of neurological involvement, she notes skin changes, similar to those which occurred in our present case, in certain of her patients. We (4) have noted changes in the color and texture of the skin of the forearms, similar to those in pellagra but without other accompanying symptoms, which occurred in a patient receiving liver extract intramuscularly for pernicious anemia, and interpreted them as related to one or more members of the vitamin B complex.

In the case here reported, certain characteristic symptoms, the history of prolonged dietary insufficiency, the changes in the skin of the hands and forearms, and the response to administration of vitamin B complex, all indicate deficiency of certain of these components. The choleystitis is believed responsible in part for exacerbations of this deficiency. Thus, it is to record an additional clinical aspect of this disease, particularly with regard to its occurrence with and recognition in the presence of cholecystitis, that this case is reported.

REPORT OF CASE

Mrs. T. H. H., a 58 year old white female had experienced attacks of abdominal pain at intervals since their onset fourteen years ago. Nine years ago, because of repeated attacks of abdominal pain, an appendectomy was done, but the attacks of abdominal pain continued and, were "the same kind as before" appendectomy. More recently the attacks had become localized to the right upper quadrant of the abdomen, and symptoms included in addition to the pain, considerable gas with abdominal distention, jaundice upon one occasion and anorexia. A diagnosis of cholecystitis had been made several years ago, based upon these symptoms but there was no operation.

During the spring of 1934, the patient noted the onset of malaise at which time she felt poorly generally, and experienced anorexia and epigastric distress. Her diet during the summer of 1934 accordingly consisted practically entirely of fruits and vegetables, with chicken the only meat and this only upon occasion.

Soon after a period of marked emotional and physical activity, incident to a change in residence, the patient noted on September 18, 1934, together with marked increase in the anorexia, a small red spot in the palm of the left hand. This same type of lesion appeared in a corresponding position on the right hand and upon the right foot about one week later. The lesions at first were red, not raised and were non-pruritic. There was no sore tongue, no edema of the ankles and no diarrhea at this time. The anorexia, marked at the time of onset of the skin lesions, improved during the intervals of freedom from the attacks of gas and abdominal distention, but recurred with exacerbations in the symptoms.

After the skin lesions had spread to involve the entire palmar surface of each hand the patient sought medical advice and the diagnosis of eczema was followed by various kinds of ointments, and X-ray treatments of the hands, but without response.

When first seen, the preceding facts constituted the history, while examination of the hands revealed marked changes. The skin of both palmar surfaces was markedly thickened, dry, scaling and there were many deep furrows present. The skin over the dorsum of either foot was pigmented. During a particularly severe attack which occurred April 17, 1935, when the patient was confined to bed for several days, there was very marked anorexia, vertigo, marked pain in the gall bladder region, and a feeling of lameness and numbness in the right leg, and an increase in depth of pigmentation of the dorsum of either foot. Most striking was the appearance of the ventral surface of the lower third of each forearm and in the

*From the Department of Medicine, School of Medicine, the George Washington University, Washington, D. C.
Submitted February 21, 1936.

antecubital fossae. Here there occurred a reddening of the skin which within a period of about ten days took on a brownish hue, the skin in these regions at the same time losing some of its elasticity and becoming studded with fine furrows, an appearance which made the involved skin seem older than the normal skin in the surrounding areas.

Positive findings in the remainder of the physical examination were as follows. The skin over the trunk and remaining portion of the extremities was of good texture and color. The heart was of normal size, rate, rhythm and with normal sounds. Blood pressure was 160/80. Slight tenderness upon palpation of the right upper quadrant of the abdomen was present but the liver and spleen were not palpable. Tendon reflexes were hyperactive.

The urine was clear yellow in color with a faint greenish fluorescence; there was no albumin, no sugar nor formed elements. Erthrocyte and leucocyte counts were normal. Gastric analysis revealed free acid from 8 to 16 units (c.c. N/10 NaOH) and total acidity 16 to 30 units. An oral cholecystogram revealed a non-filling gall bladder, while there was constantly present on the X-ray films a shadow at the site of the gall bladder, three or four times normal size; there were also several small shadows, interpreted as gall stones. Blood cholesterol determinations on May 24th and June 7th were 200 and 228 mgm. per cent respectively.

There was very satisfactory response upon the part of practically all symptoms to vitamin B in the form of brewer's yeast. On June 28, 1935, a cholecystectomy was done at which time a gall bladder containing many stones was removed by Professor Hart at the Duke University Hospital.

The patient has subsequently remained well.

DISCUSSION

The symptoms in our case agree with those reported by Elsom as indicative of deficiency in certain components of the vitamin B complex. Anorexia, one of the earliest symptoms was present practically continually in our patient, while at intervals it became very marked. It was undoubtedly responsible for the choice and limitation of dietary constituents to those substances which were more immediately palatable, but which, having a low vitamin B content, consequently produced an exacerbation of the symptoms.

The diet taken by our patient agrees well with that upon which patients studied by Elsom developed clinically obvious vitamin B deficiency. Characteristically, although it fluctuated in intensity, the neuritis became more severe at the time of exacerbation of the gastro-intestinal and skin symptoms.

The initial skin lesions, in presenting when the anorexia was particularly marked, and consisting of single red non-pruritic spots on the palmer surfaces of the hands and the dorsal surfaces of the feet, as in pellagra, behaved exactly as do similar lesions in experimental animals upon vitamin B deficient diets, and just as did the skin lesions in Elsom's patient (3).

As a manifestation of deficiency disease, there are many aspects of this case which are both of interest and importance for diagnosis and treatment. These are: first, deficiency in members of the vitamin B complex resulting from progressively decreasing intake of these substances in the diet; second, increased demand upon vitamin B substances consequent to the presence of infection; and third, decreased opportunity for absorption of important food materials (vitamin fractions) from the intestinal tract because of vigorous catharsis.

It is well, in the presence of anorexia, particularly if it is progressive, to administer the various vitamin B fractions, because otherwise a vicious circle will result. In the presence of anorexia the diet usually becomes an exclusively carbohydrate one, thus resulting in a markedly lessened vitamin B intake. If we accept Cowgill's contention that the ordinary diet is probably scarcely adequate in vitamin B substances, then the marked ill effects of continued further restriction will be evident.

In the presence of infection, coincident with the increase in general metabolic processes, it is very evident that the demand upon vitamin B substances will be much increased. In many instances the gastro-intestinal symptoms as a manifestation of vitamin B deficiency may be obscured by other etiological factors, but in a case such as the present one, the skin manifestations leave little if any doubt as to the etiological factor. The appearance of the most characteristic skin manifestations, in turn, coincident with a marked increase in the gall bladder infection upon one occasion indicates the increased demand upon vitamin B substances upon such an occasion.

That the increased rate of passage of food through the intestinal tract is a potent factor in the production of deficiency diseases, is indicated by cases of intestinal resection or of sprue. Although frequently indulged in, continued catharsis rarely seems to be responsible, of itself, for obvious manifestations of vitamin B deficiency. The catharsis in our patient was very frequent, chiefly because of the persistance of the nausea, and despite the fact that the symptoms due to vitamin B deficiency were increased, the catharsis was probably a measure of value as regards the intake of other substances in the diet.

SUMMARY

In summary, a case of vitamin B deficiency in association with disease of the gall bladder is herewith presented. The anorexia, epigastric distress, neuritis and dermatitis present during the period of the disease are discussed as regards their clinical significance. The factors responsible for deficient amounts of the several vitamin components in the various tissues are also noted and discussed.

Mucous Colitis, Complicated by Colonic Polyposis, Relieved by Allergic Management

Report of an Instance

By

L. P. GAY, A.B., M.D.
ST. LOUIS, MISSOURI

THE allergic nature of mucous colitis and its successful management by specific food elimination has been commented on by Vaughan (1) and Hollander (2). The possibility of hypersensitive reactions on all mucous surfaces has been emphasized by numerous writers. Nasal polyps are quite frequent in allergic hypersensitive rhinitis, and proper treatment by the removal of foods and inhalants tends, not only to cause their disappearance but to prevent their recurrence (3). That colonic polyposis, particularly the pseudo or post inflammatory type (4) might be a condition analagous to nasal polyposis and of an allergic nature is suggested by a case of mucous colitis complicated by colonic polyposis which was symptomatically relieved by food restrictions. That colonic polyposis does, at times, disappear spontaneously, in no way detracts from symptomatic relief in this case as symptoms can be reproduced at will. In the present case, allergic management was undertaken because of a suggestive allergic history, because of the presence of an eczema and a definite mucous colitis and to try allergic management as a last resort in the effort to prevent the necessity of the removal of the colon, as the indications for colectomy were rapidly becoming more urgent.

Mrs. N. M. B., a housewife, aged 35, had as a complaint, soreness in the rectum, obstinate constipation, and generalized abdominal pain and distention. Constipation was not a matter of hard stools but rather a difficulty in passing more than a very small amount of feces at a time. There was an increase in abdominal and rectal pain at each attempted evacuation and there was also considerable blood and mucus passed with each stool. The onset of this illness had been gradual over a period of two years, but had been getting much more severe, and the effort to secure a complete evacuation of the bowels had not only been becoming exhausting but had been consuming from three to four hours each day. At the beginning of the illness there was merely a generalized soreness of the abdomen which had progressed to a cramping pain over the entire lower abdomen with marked exaccerbations of pain before and during bowel movement. There had been a gradually increasing abdominal distention and increasing soreness of the rectum. The bowels had been normal before the onset of the pain. For some months before the onset of abdominal pain, the patient began to notice mucus in the stools which increased in frequency and quantity and for the past year had been accompanied by blood. As difficulty in evacuation increased, enemata were resorted to each day; but with results which became less and less satisfactory and several enemata were taken each day. Enemata were not expelled as a whole but there were always several small passages of water accompanied by a small amount of feces, mucus and blood over a period of several hours. As there was always a sensation of incomplete evacuation and also generalized abdominal pain and distention until the colon was emptied, several enemata were always required to give even partial relief. About six months previous to examination, the patient had been examined elsewhere and had been advised to have an appendectomy. This advice was taken and the patient was told subsequently that the appendix and an ovarian cyst had been removed. All previous symptoms had been greatly exaggerated since the operation. There had been no nausea or vomiting at any time and the appetite had been fairly good. The diet had been unchosen. There had been a loss of about twenty pounds in weight during the period of illness and there had been considerable fatigue which was unusual. The past health had always been good with the exception of a chronic sinusitis for a number of years. There had been much nasal treatment but of late the patient had discontinued treatment as she thought it seemed to aggravate her nasal condition rather than help it. There was a frontal and occipital headache at times and a pain in the back of the neck and in the right arm was usually present when the headaches occurred. The nose was always excessively moist and there had always been an excessive amount of sneezing. An itching skin eruption had been noticed intermittently and there was an itching eczema on the eye lids and about the nose. The patient's parents are living and well and there are two sisters living and well. There was no family history suggestive of allergy. The patient's husband is living and well and her one child is living and well. There have been no miscarriages. The menstruation has always been normal and regular.

Physical examination: Hyposthenic habitus, pale and undernourished. Blood pressure 120/80. There was a moderate amount of acne over the back and chest. The skin about the nose, the eye lids and the eyes was reddened and rough. There was a marked tache cerebrale. The pupils reacted to light and on accomodation. The nostrils were clear but the nasal mucosa was excessively moist. The teeth were in good repair and well kept. The throat was slightly reddened. The thyroid was not palpable. The heart was normal in size and the sounds were clear. The lungs were normal. The abdomen was distended with gas,

Symptoms:

1. Pain
2. Night Pain
3. Nausea
4. Vomiting
5. Gas
6. Bloating
7. Constipation
8. Diarrhea
9. Headache
10. Dizziness
11. Sneezing
12. Nasal Symptoms
13. Cough
14. Asthma
15. Toxemia
16. Hives
17. Eruption
18. Itching
19. Palpitation
20. Dyspnea
21. Joint Pains
22. Bruises

Directions:

Keep your diet as simple as possible. Chart your important symptoms by number in column indicating hour in which they occur. Certain foods are causing your illness, whether it is headache, arthritis, peptic ulcer, asthma or pain. The foods responsible can be determined by a careful diary. Your cooperation is essential for success. List visits to barber shop, beauty parlor, theatre, etc. List anything unusual. Do not take any medicine not prescribed.

Remarks:

X. Symptoms persist.
XX. Symptoms exaggerated.
Z. Symptoms relieved.

These foods are to be omitted:

Date					Date					Date				
Breakfast	1st hr.	2nd hr.	3rd hr.	4th hr.	Breakfast	1st hr.	2nd hr.	3rd hr.	4th hr.	Breakfast	1st hr.	2nd hr.	3rd hr.	4th hr.

Dinner					Dinner					Dinner				

Form 1—Dietetic "Diary" devised to enable patient to record effects of foods upon symptoms, etc.

and, though there was generalized tenderness throughout, there were no organs palpable. There was a midline post operative scar.

Sigmoidoscopic examination made by Dr. Leith H. Sclocum, who referred the patient was reported as follows: Unable to proceed beyond five and one-half inches. At this level, the lumen of the bowel was apparently narrowed and turned abruptly to the left. The mucous membrane at this point shows what appears to be a polypoid formation. There is no bleeding around the polypoid area. The mucous membrane below this point is fairly normal except that it is congested. The first and second Houston valves appear normal. There are two hypertrophied papillae seen in the anal canal and there is also a slight fissure which is to be seen posteriorly. Report dated September 23, 1934.

A barium enema done at this time showed a very marked and extensive polyposis throughout the colon. This is shown in Figure 1. The urine was entirely negative. The blood picture was that of a moderate degree of secondary anemia.

Protein tests were done by the intracutaneous method and those foods which produced the most pro-

Fig. 1. Barium enema with air injection showing extensive polyposis throughout colon. September 11, 1934.

nounced reactions were eliminated from the diet. The restricted foods were beet, cauliflower, chicken, coffee, corn, pepper, pork, white potato, rice, salmon, sweet potato, and wheat. The restrictions were imposed on September 20, 1934. After a trial of one week there was little or no appreciable change. After another week of the same routine, the only change was that the eruption was a little worse. It was noted that milk had been taken more freely during the two preceeding weeks than had been the usual custom, so milk was added to the proscribed list as an experiment. In the meanwhile a form of diary (Form 1) had been devised for this patient in order to keep a more accurate record of her symptoms during the day after the ingestion of each meal, as it was felt that positive skin tests were of little value as a means of specific diagnosis of allergens. On October 11, 1934, the eruption had about cleared up and the patient reported that the bowels were moving occasionally without recourse to an enema. One week later the skin eruption had disappeared entirely and the patient considered that the bowels were from 50 to 75% better, and though there was mucus in the stools, that the blood had disappeared. From October 22 to October 27, the bowels moved thoroughly and adequatey without an enema. There was abdominal pain and distention on October 27, which was relieved by an enema. It was recorded in the diary that tomato had been eaten on that day for the first time in five days. Tomato was removed from the diet and wheat and rice were added. A later feeding of tomato proved that it was an actual allergen. In the same manner it was found that egg was also a factor and that progress was more apparent after its removal. Milk and egg were replaced in the diet on November 30, 1931, in order to prove them as allergens and as a result, the eruption reappeared, there was an increase in abdominal discomfort and an increase in mucus discharge. During the next few weeks milk, egg, pineapple, banana, and tomato had been proved by clinical trial to be able to increase symptoms, so they were all permanently removed from the diet. From this time on each food of ordinary use was replaced separately in the diet and careful note was made of its effect. White potato and pork were proved to be allergenic and again progress was more apparent after the total elimination of these foods. On February 7, 1935, the patient reported that she felt perfectly well and as though there was nothing at all the matter with her. The bowels were moving each day without difficulty and mucus was appearing in the stools at rare intervals only. It was observed that mucus appeared only if wheat was eaten consistently or if the diet was broken deliberately. Wheat apparently had an accumulative action that could be avoided by including it in the diet no oftener than every fifth day. By February 14, there was no longer any evidence of polypi by sigmoidoscopic examination, and by barium enema there was a definite diminution of the original number of polypi throughout the colon. Sigmoidoscopic examination by Dr. Leith H. Sclocum made February 25, 1935, was reported as follows: Patient again examined, and while I am still unable to get into the sigmoid, the polypoid formation noted in the previous report is not present. The mucous membrane throughout is entirely normal. The anal canal presents the findings noted in the previous report.

Periodic examinations by barium enema have been made and serve as an index to the clinical improvement of this patient as they demonstrate a steady decrease in the number of polypi. Films, taken at vary-

Fig. 2. Barium enema with air injection made February 14, 1935.

Fig. 3. Barium enema with air injection made July 22, 1935.

Fig. 4. Barium enema without air injection made September 8, 1935.

ing intervals, by means of the opaque enema are shown. The patient has regained her lost weight and is perfectly comfortable as long as she remains within her dietary limitations. Restriction of specific foods in this case has had the effect of relieving not only the major complaints but also the two minor ones of eczema and hypersensitive rhinitis. As there has been no effort made to avoid contacts and inhalants it follows that the relief obtained from nasal symptoms was due to restriction of foods that were producing inflammatory reactions in other mucus tissues. The etiological factors in this case of mucous colitis have apparently been removed by the elimination of a few foods, which, when re-introduced into the diet cause a prompt return of abdominal pain associated with the presence of mucus in the stools. Removal of these irritants has been accompanied by the cessation of all symptoms of colitis and by an apparent diminution of colonic polypi. In this instance it seems that the specific treatment of colonic irritation has indirectly been helpful in the eradication of a majority of colonic polypi just as specific treatment of hypersensitive rhinitis tends to promote the disappearance of nasal polypi and to prevent the recurrence of those which have been removed surgically.

A new form of food diary which is self explanatory and which permits an hourly and daily record of symptoms after meals was devised for this patient. The diary is useful in any type of allergy and constitutes an accurate and permanent record of the individual's reaction to a compatible diet, to trial diets and to suspected foods purposely included in the diet.

Selenium-Toxicosis: the Etiologic or Causative Factor in Pellagra?

By

R. de R. BARONDES, M.D.
SAN FRANCISCO, CALIFORNIA

SELENIUM *(Se = 79.2)*, and other like non-metallic compounds as tellurium, etc., belong to the sulphur group. Selenium occurs in various blends and minerals, three allotropic forms being known at present. The chief source of the element is iron pyrites in which part of the sulphur content is replaced by selenium, though it may be widely distributed throughout nature associated with sulphur in some form. In the pure state, selenium is steel-grey in color, is a good conductor of electricity when exposed to light but a poor one when in the dark. It is very sensitive to light, possesses the power of fluorescence, which property seems to bear some connection with its ability to photosensitize. In this respect it resembles the iron-free photodynamic substance "hematoporphyrin" which is sometimes found in the body under abnormal conditions, and which may be made synthetically by the action of sulphuric acid on hemoglobin. There appears to be some relationship between selenium and other fluorescent compounds such as "chlorophyll-zeochin" a substance found in corn, and to "flurophile" which is found in the bodies of certain animals dying of the disease "fagopyrism."

According to Gassmann (1), selenium is found in the human body in minute amounts, healthy teeth containing about 0.056%. Selenium is also to be found in the urine, 0.0011% in males, and 0.00009% in females. He offers no explanation why the greater amount is found in male urine.

The physiologic action of selenium and its compounds has been little studied or understood. Selenium itself apparently exerts no poisonous action but the alkali selenites, and selenates, are very poisonous. This toxic effect resembles that of arsenic and fluorite poisonings.

Selenium Oxide (SeO), when given internally in minute amounts, appears to carry oxygen to the body sulphur, combining with it, and does not easily lose its effectiveness as an oxydizing agent. This compound in the system will cause an increased sulphuric acid secretion and for this purpose has been used in the treatment of malignant diseases, as it is known there is a diminution of this acid in those diseases.

Selenium Oxychloride ($SeOCl_2$), another selenium compound, has very peculiar and uncommon solvent properties. It has a selective solvent action on such resistant materials as hair, silk, rubber, enamel, "bakelite," the hydro-carbons, etc. It appears also to have a solvent effect on the outer coverings of the grains (buckwheat, corn, maize, rice, etc.), and perhaps adversely affects the vitamins contained therein.

Selenium compounds are known to destroy the diastasic-like action of saliva (2). They also have been used in the treatment of amebic infections, being known to kill the *endameba hystolytica*. This effect is probably due to the solvent action of the compounds on the outer cellulose-like coat or ectosarc of the ameba, and perhaps also to some photosensitizing affect on the ameba itself which is very light-sensitive.

When animals have eaten plants poisoned by selenium, they become crippled, and die in great numbers especially on being exposed to the bright light of the sun. The disease "blind staggers," and "alkali disease" found among live-stock has definitely been traced to this toxic irritant substance, selenium (3). Animals apparently are able to detect the plants containing lethal doses of the poison and leave them alone, but certain species of leguminous plants and grains, which they do eat may contain dangerous amounts of the toxic substance. Though the amount of the poison taken into the body may be small, the long and continued ingestion would no doubt lead to a toxic accumulation in the body.

So close a relationship exists between selenium and sulphur that plants are unable to distinguish them apart, utilizing the one when the other is absent from the soil. The remedy of this situation, as pointed out by the United States Department of Agriculture, is to add sulphur to the seleniferous soil, that the undiscriminating plants will get a great deal more of it than they do of selenium. The amount of this toxic element diminishes in proportion to the amount of the sulphur added.

A marked resemblance will be noted on comparing the symptoms of selenium-toxicosis in animals to the symptoms of pellagra in man. The most striking of these are:

1. Both suffer severely from gastro-intestinal disturbances, nervous and mental disorders which often terminate in complete dementia.

2. On exposure to the bright light of the sun during the Spring and Summer months, skin manifestations present themselves in the form of vesiculations and actinic dermatites. The other symptoms present become more aggravated, and it is at this time the mortality is at its highest.

3. During the Fall months, the skin commences to desquamate, and by wintertime atrophic and pigmented areas resembling vitiligo make their appearance. (In man, if these pigmented patches make their appearance on the back of the hands and forearms, suspicion of pellagra should be immediately aroused).

4. The pellagrins, in addition to a capricious appetite or anorexia, complain also of a burning sensation of the tongue and throat, and there is often a complaint of a garlic or arsenic-like odor in the mouth and breath. A somewhat similar offensive odor is noted on and about selenium poisoned animals. This odor is probably due to the carbon di-selenide or methyl selenide, and closely resembles the smell of de-

Submitted January 17, 1936.

cayed radishes. It is said carnivorous beasts will not eat the flesh of animals poisoned by selenium on account of the presence of this obnoxious odor.

Another disease among animals (dogs) known as "black-tongue" corresponds closely with the geographic distribution of pellagra. Goldberger was able to produce in dogs an experimental condition similar, if not identical with pellagra, by a type of diet found to be associated with the occurrence of pellagra and which had caused pellagra to be produced in the human (4). He concluded though the factor P-P, now called vitamin G or B_2 was the controlling factor in pellagra, and in "black-tongue."

It is known that certain chronic alcoholics develop typical symptoms of pellagra after imbibing the cheapest of whisky or so-called "corn." If this liquor should be made from grains and plants that have been poisoned by selenium or similar poison, more or less of the toxic substance would find its way into the liquor, setting up a chain of symptoms, especially in those with a lowered tolerance to such a poison, thus accounting for the so-called alcoholic-pellagra syndromes.

Pellagra has generally been ascribed to a lack of sufficient pellagra preventing substances in the diet, but the factors underlying this deprivation are many and various. As early as 1776, Venice passed legislative measures prohibiting the sale or exchange of all ill-smelling, ill-tasting and discolored corn. Even to this day, the hypothesis is that corn and like foodstuffs lack something essential to the proper nutritional rhythm of the body; in other words, they are "deficient" (5). In the South, where there is a large rural population of the poor laboring class, pellagra should be expected, but in Mexico, where the economic and social conditions of the rural people are similar to our potential pellagra population, there is comparatively little pellagra (6).

Why pellagra should become so prevalent, even on the increase, when the knowledge of vitamins and nutrition is now so well understood, remains unexplained. Statistics show today that over 30% of large groups of hospital patients die or go into chronic progressive illness in spite of what appeared to be ample opportunity of vitamin therapy to have been effective (7).

This rather poor showing of vitamin therapy in pellagra would only point to a cause other than one of a nutritional deficiency.

It is known that a diet of animal flesh, liver, salmon, egg-yolk and leguminous vegetables possess curative and preventative powers in pellagra. These foods are all rich in sulphur. As there is a disturbed sulphur metabolism in both pellagra and selenium poisoning, and, as sulphur has an affinity for selenium and *vice versa*, the administration of sulphur and diet rich in sulphur-containing foods would appear to be the proper curative and preventative measures to be instituted for both these disorders.

It is surprising that no extensive searches have been undertaken on the food and soil of pellagrinous districts to determine the presence and concentration of such toxic substances as selenium that might be the etiologic or causative factor of pellagra (8).

CONCLUSIONS

The present state of knowledge concerning the cause of pellagra is still unsatisfactory.

The rather poor showing of vitamin therapy in pellagra would only point to a cause other than one of a nutritional deficiency.

A striking resemblance is to be noted between the symptoms of pellagra and selenium poisoning, and there is reason to believe this disease is the result of a similar poisoning. The toxic poisoning is absorbed from the food in the alimentary tract and spreads throughout the body, concentrating principally in the liver where it does the greatest damage. That it acts perhaps as an oxydative catalyst by causing the destruction of certain vital food constituents by oxydation, or by preventing the proper absorption, assimilation or utilization by the body of the food in an adequate manner may be possible.

The actinic dermatitis present in these cases, and excited by exposure to sunlight could be due to the fluorescent substance, hematoporphyrin, or some similar-acting photodynamic substance in the bloodstream which is capable of sensitizing the skin to sunlight. This substance is apparently manufactured in the body as the result of the action of the toxic substance (selenium?) on the body sulphur whereby the resultant increased sulphuric acid of the body acts on the hemoglobin forming the photo-sensitizing substance.

As there is a disturbed sulphur metabolism in pellagra, a diet that is rich in sulphur, and the institution of sulphur therapy, would appear to maintain immunity against the disease. If, on the other hand, the body tissues should be so extensively damaged and beyond Nature's repair, then any food, vitamin, or for that matter, any therapeutic measures would be unlikely to restore structures so injured and would be of no avail.

Chemical examinations and spectroscopic analyses should be made of the foods and soils in pellagrinous districts to determine the presence, and concentration, of any and all toxic substances, that the proper study of toxic limits, tolerance limits, diagnostic symptoms, and remedial measures could be undertaken thus safeguarding the public health within the areas affected.

ADDENDUM: Even if the basis of this new theory should prove incorrect, and fall by the wayside along with the many other theories thus far advanced—nevertheless it should only spur one on to greater intensive research in solving the problem, the cause and the cure of pellagra.

II. Effect of Prolonged Administration of Salicylate Upon Nitrogen Metabolism and Plasma Carbon Dioxide Combining Power in the Dog*

By

J. G. SCHNEDORF, M.D.

and
A. C. IVY, M.D.
CHICAGO, ILLINOIS

A REVIEW of the literature indicates that the administration of salicylates increases nitrogen metabolism (1-8). Some observers report a subsequent compensatory decrease during the post-administration periods (9-11). However, Jolin (12) reports that salicylates have no influence and Wiley (13), Morris and Graham (14) report that salicylates exert a slight inhibitory effect on nitrogen metabolism. Our work was done in an endeavor to clarify the literature on this point, and to determine if calcium gluconate in any way influences the effect of acetylsalicylic acid on nitrogenous metabolism. At the same time we studied the effects of acetylsalicylic acid and a mixture of acetylsalicylic acid and calcium gluconate on the carbon-dioxide combining power of the plasma which several observers (15-18) have reported to be lowered by the drug. Calcium gluconate was chosen because of its basic ash and because it ameliorates the gastric irritation caused by acetylsalicylic acid (19), without significantly depressing gastric secretion (20).

METHODS

Two groups of normal female dogs were employed. After ten days on a standard diet, seven daily control determinations were made on 24 hour samples of urine and upon the CO_2 combining power of the blood plasma. Residual urine was obtained by catheterization.

The first group of four dogs then received 0.15 Gm. of Merck's U. S. P. acetylsalicylic acid per kilogram body weight *twice* a day for two months. The second group of three dogs received a similar amount of acetylsalicylic acid with 0.07 Gm. per kilo of calcium gluconate twice a day for the same period. When vomiting occurred the drug was given only *once* a day, and the metabolic results under such conditions were discarded. During the period of medication, determinations on the blood and 24 hour urine were made three or four times a week.

RESULTS

Group I. Prolonged daily administration of acetylsalicylic acid resulted in alterations of nitrogen metabolism, as determined by urinary analysis, and of the carbon dioxide combining power of the blood plasma.

The dogs of Group I on acetylsalicylic acid alone developed nausea and vomited on about the third day of medication. To prevent vomiting the dosage was decreased by one-half for one or two days after which the full dose was resumed. Anorexia prevailed for some time but did not prevent the dogs from completely eating their standard meal. The results of analysis were discarded on days when the animals vomited. In this group there resulted first a decrease in total nitrogen output of 11% below normal (dog 1, 17.4% decrease) for the first 20 days and of 6.2% below normal for the second period of 25 days, which was followed by an increase of 15.2% above normal during the third period of 14 days. Urea elimination followed a parallel course; there was a progressive decrease in the total urea output; first period, —10.7%; second period, —24.9%; and then a rise to +117% during the third period. It was found that the ammonia output also decreased 16.4% below normal during the first period and rose to 4.9% above normal in the second period. If the data are not divided into such periods, the average output for the entire treatment period is the same as the control period; that is, the increase during the last two weeks of medication was adequate to annul the decrease observed during the first six weeks.

These dogs showed a definite tendency toward acidosis. The average plasma—CO_2—combining power of dog one was 44.5 vol. per cent; on acetylsalicylic acid medication, it fell during the first period to 37.9, during the second period to 39.4 and then returned to 44.5 during the third period. The pH of the urine showed parallel changes, becoming lowest during the first period of medication and then gradually rising above normal in the third period. The average volume of urine as well as the total output of urinary chloride was decreased under medication with acetylsalicylic acid.

Group II. The administration of calcium gluconate with acetylsalicylic acid to the dogs of group two

allay some of the effects produced by the administration of acetylsalicylic acid alone. Nausea and vomiting were delayed or occurred on about the sixth day of medication, and the anorexia was less in degree. Nitrogen metabolism was stabilized; during the first period (first 20 days) of medication the average total nitrogen output was decreased only 2.8 % below normal, while during the second period it rose to 7.8% above normal, and during the third period it was 5.1% below normal. The ammonia and urea output likewise did not show marked variations from normal.

No tendency toward acidosis was evidenced by the determination of the plasma—CO_2—combining power; the latter instead rose from 44.0 to 47.0 during the first period, and then fell to 44.2 and 43.5 during the second and third periods respectively. Associated with this the urine remained alkaline.

The average volume output of urine and the total output of chloride was slightly increased during medication with acetylsalicylic acid and calcium gluconate.

DISCUSSION

Undoubtedly an important factor concerned in the early decrease in urinary nitrogen elimination is the digestive disturbance caused by acetylsalicylic acid. After the first few days the animals became more tolerant to the drug, as evidenced by the absence of vomiting, and later the disappearance of anorexia. After about thirty days the nitrogen elimination returned to normal and then after about forty-five days it was above normal. This phasic reaction may be explained adequately by the early more acute disturbance of digestion causing a decreased nitrogen absorption with a slow return to normal which was then followed by a compensatory increase in the urinary nitrogen as a consequence of the true action of the drug on nitrogenous metabolism. As stated above, this phasic or periodic reaction of nitrogenous elimination would have been overlooked had the data on nitrogenous elimination during acetylsalicylic acid administration been averaged and compared with that of the control period. The foregoing interpretation is supported by the fact that the administration of calcium gluconate definitely decreased the objective digestive symptoms. After the slight digestive disturbances had disappeared, the effect of the acetylsalicylic acid was to augment nitrogenous elimination in the urine slightly but definitely, which would appear to be the true effect of the drug on nitrogenous metabolism.

The administration of acetylsalicylic acid in the doses employed caused a slight but definite "acidosis" during the periods that the digestive disturbances were present, it being more evident during the period of more marked disturbance. Correlated with the decreased plasma—CO_2—combining power, the urine became acid and there was a decreased ammonia coefficient. The acidosis is best ascribed partly to the acid properties of the acetylsalicylic acid and partly to its early toxic action upon the liver and kidney inhibiting normal deamination with an accumulation of amino acids in the blood. The calcium gluconate prevented the "acidosis" partly because of its basic ash and partly because it prevented disturbances of digestive function and deamination of amino acids. As the animals developed a "tolerance" to the dose of acetylsalicylic acid used, there was more complete absorption of nitrogen in the food so that nitrogenous elimination in the urine increased while more complete

deamination was adequate to compensate for the "acidosis."

The foregoing interpretation of the evidence, we believe, is the most simple and direct view of the effect of calcium and is preferable to the alternative hypothesis that the calcium in some way improved in the early periods tissue metabolism of nitrogen. This leads us to the view that the true effect of acetylsalicylic acid on nitrogenous metabolism of the body tissues is to increase it. Thus, we maintain that the results of those who have reported a decrease in nitrogen metabolism on salicylate administration, are due chiefly to digestive disturbances leading to a decrease in the absorption of nitrogenous food stuffs from the intestine.

It is pertinent to point out that Mutch (21) has reported that mildly toxic doses of calcium-acetylsalicylate given with traces of calcium chloride interfere less with the ossification of cartilage and the growth of young rats than do equivalent amounts of acetylsalicylic acid itself.

SUMMARY AND CONCLUSIONS

1. Prolonged daily administration of acetylsalicylic acid (0.15 Gm. per kilo twice a day) resulted in digestive disturbances, alterations of nitrogen metabolism and a tendency toward acidosis in dogs. The average total nitrogen output on continued medication was decreased 11% below normal during the first twenty days, 6.2% below normal during the following twenty-five days and was increased to 15.2% above normal during the following fourteen days. "Acidosis" was evidenced during the first two periods by a decreased plasma-carbon-dioxide-combining power, an acid urine and a decreased ammonia coefficient.

2. The administration of calcium gluconate (0.07 Gm. per kilo twice daily) with the acetylsalicylic acid ameliorated the untoward effects of acetylsalicylic acid. Nitrogen metabolism was stabilized as evidenced by a more uniform output of urinary nitrogen. Early acidosis was prevented; the plasma carbon-dioxide combining power increased slightly, the urine remained alkaline while the ammonia coefficient was not decreased to such a degree as it was with acetylsalicylic acid alone.

3. It is concluded that the decreased nitrogenous metabolism reported by some observers is due chiefly to digestive disturbances and the true effect of acetylsalicylic acid on nitrogen metabolism is to augment it slightly when large doses are administered.

Glutamic Acid Hydrochloride as a Substitute for Dilute Hydrochloric Acid in Achlorhydria*

By

PAUL H. WOSIKA, M.S., M.D.

CHICAGO, ILLINOIS

All investigators who have studied the problem of artificially administering hydrochloric acid agree upon one point, i.e., that it is impossible to duplicate the continuous secretion in the stomach by substitution therapy [6, 8, 16]. However, the indications for the use of this acid are numerous and seem to be increasing as indicated by frequent reports of its beneficial effects. The symptoms of "dyspepsia" have been given as indications for the use of HCl [14], [15], [17]. Hydrochloric acid has been recommended in chronic cholecystitis [1], asthma [3], [7], prophylactically in the curative course of the stomach [12], pernicious anemia [5], sciatic disease [20], eczema [21], typhus [22], and acne vulgaris [4]. While there is a decided amount of abnormal acid in the stomach contents

The use of HCl is not without its dangers to the teeth [23] unless it is well diluted and an alkaline mouth wash is used afterward to neutralize it. For this reason, preparations have been sought which would deliver acid to the stomach yet could be taken in tablet or capsule form. Glutamic acid hydrochloride is one of these preparations.

Glutamic acid has been found to have antiacetonuric effects [2], [9] when used in conjunction with iron. However, other authors [10], [18] were unable to substantiate the hemopoietic stimulating effect. Tarozzi [21] and Mellon [19] considered that glutamic hydrochloride does not stimulate to the secretion of HCl. However, since no report could be found in the literature showing the concentration of acid produced in the stomach by this preparation, the present study was undertaken to determine the effectiveness of glutamic acid-HCl in liberating free HCl in the stomach. It can be administered easily, and if it proves to be as effective as dilute hydrochloric acid then the disagreeable taste and danger of dilute acid can be avoided.

METHOD

A group of 19 patients with achlorhydria were selected from the Medical Clinic of Northwestern University. The group contained 8 patients with pernicious anemia, and 7 of the entire group were men. The ages of the patients averaged 60 years. In most instances a histamine gastric analysis had been performed, but this was repeated to insure that these patients did not secrete HCl. One-tenth milligram of histamine hydrochloride was injected subcutaneously for each 10 kilograms of body weight. Besides the fasting contents, the total amount of secretion was withdrawn every 20 minutes for 80 minutes. In no case was acid found. Titrations for free and total acid were performed in the usual manner and the pH was determined by the quinhydrone electrode.

In order to study the effectiveness of the glutamic acid, the patients returned to the clinic about once a week and the fasting contents of the stomach were removed. Glutamic acid hydrochloride capsules were given with 200 c.c. of tap water, since tap water was found on numerous occasions to have a pH more nearly 7.00 than did any available distilled water. Specimens

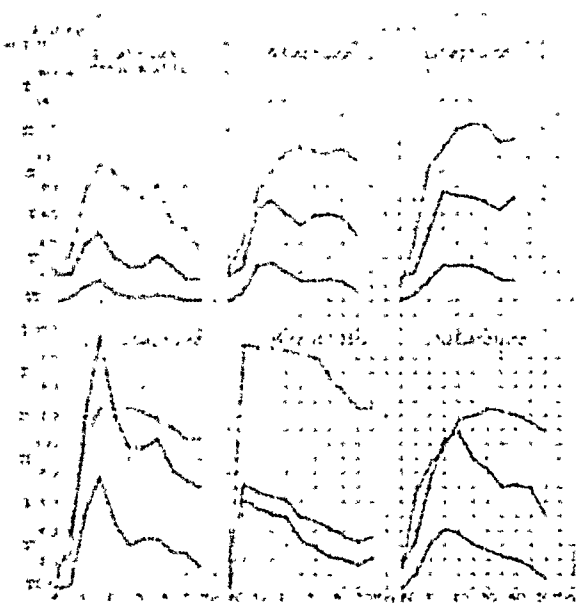

Fig. 1. Average free and total acid (solid lines) and pH curve (broken line) on 17 to 19 patients with achlorhydria. 200 c.c. water used with each test.

of 6.0 c.c. were removed every 5 minutes until the stomach was empty. In but few instances was it possible to get specimens after 50 minutes, which meant that 60 c.c. of the original 200 c.c. had been removed through the tube and the remainder presumably had gone through the pylorus. Five c.c. were used to determine the pH, and 1.0 c.c. was necessary for the titration of free and total acid. The titrations were carried out with N/30 sodium hydroxide because of the small amount of material, and the data then recalculated to the usual "clinical units."

The patients were given 1 capsule of glutamic acid-HCl on one day, 2 capsules on the next visit, and so on

up to 10 capsules. Only one test was performed on one day. In one test, 4.0 c.c. of dilute HCl (U.S.P.) were injected through the tube with 200 c.c. of water. Specimens were withdrawn similarly. This is the usually recommended dose of HCl.

The amount of glutamic acid in each capsule is 0.28 grams, which should deliver 8.45 minims of acid equivalent to the usual 10 per cent hydrochloric acid. Therefore, 7 capsules should equal the dilute HCl in one teaspoonful.

RESULTS

The results of the determinations were averaged and the curves derived are shown in Figure 1. Each line shown does not represent the average of the same number of analyses because of the difficulty encountered in having patients return for the tests. However, in no instance were data on less than 12 patients used; the largest number was 19.

Figure 1 shows the average effect of 2, 4, 6, 8 and 10 glutamic acid hydrochloride capsules and the results when 4.0 c.c. of dilute hydrochloric acid were used. The alternate curves representing the results with 1, 3, 5, 7 and 9 capsules are available but are not included here, since they are no more informative than those presented. Throughout Figure 1 the average free and total acid curves are represented by solid lines and the pH by broken lines. In general, as might be expected, the acid values increased when larger numbers of capsules were administered. Eight capsules produce on the average the greatest concentration of free and total acid in the stomach. which was higher than when 4.0 c.c. of dilute HCl were used. When 10 capsules were given the acid values were lower than after 8 capsules; this must be ascribed to variation within the limits of accuracy of the procedure, since these two curves are averages of results on the same group of patients. Such variations are commonly present when gastric analysis figures are compared.

The results suggest that 8 capsules of glutamic acid-HCl produce the highest free and total acid for the 200 c.c. dilution used. However, it should be remembered that the total difference in acid administered on any two alternate tests was equivalent to only 17 minims of HCl.

When 6, 8 or 10 capsules were administered, the average pH reached approximately 3.0 and was maintained there for the 50 minutes that the material was in the stomach. The curve reached its height at the end of 10 minutes. A pH of 1.0 was attained when the dilute HCl was given. This level may be inferred to have been reached immediately, and the acid emptied slowly from the stomach. From a bactericidal standpoint (13) this level (pH 1.0 to 2.0) would be desirable, but it should be remembered that these figures merely represent the acid present in a dilution of water and stomach secretion. This amount would be quickly neutralized if only a small quantity of food were consumed.

COMMENT

When individual patients are considered, there are wide divergences in the acid values developed following the administration of these capsules. Thus, arbitrarily selecting the results when 8 capsules were used and considering the specimens obtained 10 minutes after the ingestion of the capsules, one patient showed: pH 1.70, free acid 230, and total acid 400. Another patient showed: pH 7.03, free acid 0, and total acid 15 for this same 10 minute period. The latter patient attained his greatest concentration of acid at the end of 20 minutes: pH 2.10, free acid 65, and total acid 173. Throughout the entire study similar wide variations were noted. Variations also occurred following the administration of dilute HCl but were not so extensive. The maximum acid values attained by individual patients receiving 8 capsules were observed on the tenth to the fortieth minute period.

A free acid reading of 230 seems high and might be thought to be dangerous to the lining of the stomach. However, Mahler (19) studied the effects of this preparation and observed the action on the gastric mucosa through a gastroscope. He could find no ill effects.

It would seem that the capsules may not have disintegrated so quickly in some patients as in others. When the capsules were put into warm water and the containing vessel slowly rotated, it was noted that 2 or 3 minutes were necessary for the capsule to break up and 5 or 6 minutes elapsed before most of the glutamic acid-HCl went into solution. However, all the material did not leave the capsule. By inference, it may be assumed that some of the hydrochloride may have passed undissolved into the intestines.

Another reason for the differences in individual readings was due to the failure of mixing the acid with the water and the stomach contents. Perhaps this difficulty might have been overcome by withdrawing all the contents at each 5 minute interval and replacing all but the 6.0 c.c. necessary for the determinations. This was not done, and would not be done if patients were given these capsules for therapeutic purposes to take in place of the fluid hydrochloric acid. At best, an imperfect mixing of acid must result when capsules are ingested.

The question of the advisability of using HCl in therapy will not be discussed. The indications, both past and present, are numerous. It must also be appreciated that substituting hydrochloric acid in amounts equivalent for the normally present acid is still impossible. However, it must occur to everyone that there are advantages in the use of capsules when acid is to be prescribed. Concentrations of acid can be developed with the use of these capsules equal to and greater than can be found with the usually recommended dose of 4.0 c.c. of HCl. The convenience of this method has much to commend it. It is easier to swallow several capsules than to sip acid through a straw, particularly when the many cautions given the patient with the prescription for fluid acid make him fearful.

When the capsules were given to patients with hypochlorhydria, no great stimulation of acid was found. This is contrary to the findings of Tagawa (24) and Mahler (19).

A prolonged clinical trial to test the possible beneficial effects of the glutamic acid hydrochloride was not done. However, from the present results it would seem that for a dilution of 200 c.c. 8 or 9 capsules should be used.

SUMMARY

This study of 19 patients with achlorhydria permits the observation that using 8 or 9 glutamic acid hydrochloride capsules (0.28 gm.) with a glass of water (200 c.c.) produces free, total, and pH readings that

compare favorably with the results of 4.0 c.c. of dilute hydrochloric acid.

Note: Miss Florence Burdahl gave expert technical assistance.

The author wishes to express his appreciation for the helpful criticisms and suggestions of Drs. Charles A. Elliott, Clifford J. Barborka, and Lathan A. Crandall in the preparation of this manuscript.

Phenolphthalein Studies*

III. Phenolphthalein and Activated Charcoal

By

BERNARD FANTUS, M.D.

and

J. M. DYNIEWICZ

CHICAGO, ILLINOIS

THE wisdom of the introduction, in the 11th edition of the United States Pharmacopoeia, of Activated Charcoal instead of mere charcoal and of making efficiency rather than source the criterion for its official standing, is well illustrated by the relation of phenolphthalein to charcoal: for charcoal that would have been acceptable in accordance with the U. S. P. X requirements may be entirely worthless as an adsorbent of phenolphthalein, while activated charcoal, U. S. P. XI, is an active adsorbent of phenolphthalein.

The idea having been expressed that charcoal is a useful remedy in cases of phenolphthalein overdose, experiments were undertaken with several kinds of charcoal we had on hand in the laboratory and that would have satisfied the requirements of the Xth edition of the U. S. P. with the following results (Table I, Part A).

It will be seen that none of these varieties is likely to have much antidotal value in phenolphthalein overdose, as they merely adsorb from 0.1 to 1+% and it will also be seen that none meet the requirements for activated charcoal U. S. P. XI: these being as follows:

"Dissolve 0.25 Gm. of methylthionine chloride in enough distilled water to make 250 c.c. of solution. Measure exactly 50 c.c. of this solution, at 25° C., into each of two 100-c.c., glass-stoppered flasks. Add to one flask exactly 0.25 Gm. of activated charcoal, stopper the flask, and shake it vigorously for five minutes. Filter the contents of each flask through a filter, which has not been previously moistened, rejecting the first 20 c.c. of each filtrate. Measure exactly 25 c.c. of the remaining filtrates into each of two 250-c.c., volumetric flasks. Add to each flask 50 c.c. of an aqueous solution of sodium acetate (1 in 10) and mix thoroughly, then add from a burette 35 c.c. of tenth-normal iodine, keeping the mixture in constant rotation. Stopper the flasks and allow them to stand for fifty minutes, shaking them vigorously at intervals of ten minutes. Dilute each mixture to exactly 250 c.c. with distilled water,

*From the Laboratory of Pharmacology and Therapeutics, College of Medicine, University of Illinois, and assisted by a grant from Phenolphthalein Research, Inc.
Submitted April 2, 1936.

mix thoroughly, allow to stand for ten minutes, and filter each through a filter, which has not been previously moistened, rejecting the first 30 c.c. of each filtrate. Determine the excess of iodine in 100 c.c. of each filtrate by titration with tenth-normal sodium thiosulfate. Calculate the number of cubic centimeters of tenth-normal iodine consumed in each titration: the difference between the two titrations, multiplied by 5, amounts to not less than 3.5 c.c. (adsorptive power)."

TABLE I

M. Activated Charcoal, M.	6.27	13.36	3.6
N. Activated Charcoal, M.	6.84	14.57	3.98

It will be seen from Table I, Part B, that the charcoals that meet the U. S. P. XI requirements also display activity in the adsorption of phenolphthalein and that the adsorption of phenolphthalein is proportionate to the degree of methylene blue adsorption, as is well shown by Graph I. This fact has been expressed by Freundlich's rule, which postulates that "different varieties of charcoal show the same order of adsorbing power for different substances" (1).

It is also evident from Graph I that charcoal is approximately four times a better adsorbent for methylene blue than it is for phenolphthalein under the conditions of the experiment: for it will be noted that the percentage adsorbed from 40 mg. of methylene by 0.25 Gm. of charcoal is practically the same as that adsorbed from the same quantity of phenolphthalein by 1.0 Gm. of charcoal.

In the interpretation of the Table as well as of the graph, three factors must be brought out that would alter the results: (1) the hydrogen-ion concentration, (2) the length of time of exposure to charcoal, and (3) the temperature.

HYDROGEN-ION CONCENTRATION

The influence of hydrogen-ion concentration on the adsorption of phenolphthalein is of considerable practical interest, inasmuch as the adsorptive activity of the charcoal when employed to nullify the effect of overdose would be carried on at the pH of the alimentary tract.

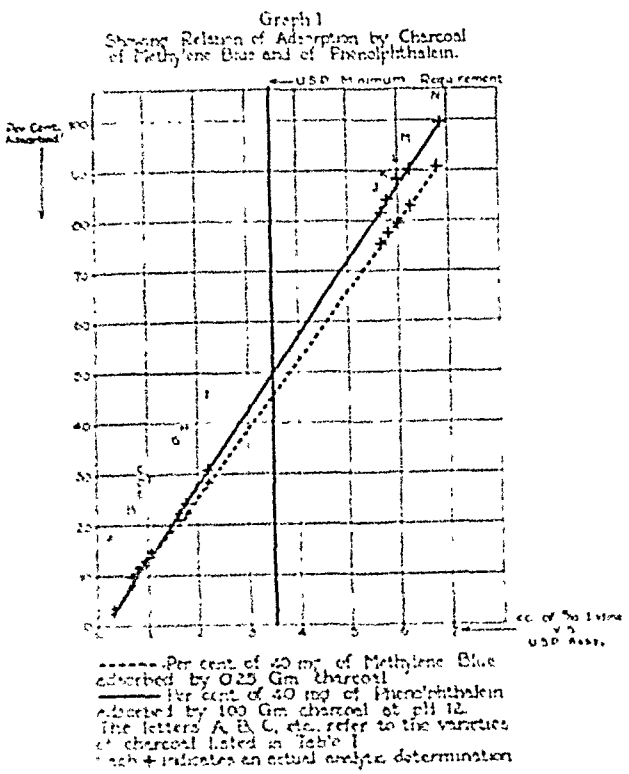
To determine what quantity of charcoal is likely to be required to adsorb almost 100% of 0.010 Gm. of phenolphthalein in 100 c.c. of buffer solution, observations were carried on at a pH of 9.0 with different amounts of charcoal. Results are shown on Graph 2. From it, one notes that it requires 0.060 Gm. of charcoal to adsorb almost 100% of 0.010 Gm. of phenolphthalein from its solution at this hydrogen-ion concentration.

When we compare the amount of activated charcoal of best quality (N) required for almost complete adsorption at varying hydrogen-ion concentrations, we arrive at results shown in figures in Table II and graphically in Graph 3.

TABLE II

Showing Amount of Activated Charcoal (N) Required for Almost Complete Adsorption of 0.010 Gm. of Phenolphthalein in 100 c.c. of Buffer Solution (2)

At pH 8.0, amount of charcoal required	0.050 Gm.
At pH 9.0, amount of charcoal required	0.060 Gm.
At pH 10.0, amount of charcoal required	0.080 Gm.
At pH 11.0, amount of charcoal required	0.120 Gm.
At pH 12.0, amount of charcoal required	0.200 Gm.



It will be seen from Table II and Graph 3 that the amount of charcoal required to adsorb a given quantity of phenolphthalein is much less at pH 8.0 (which might be considered a point near the alkalinity of the bowel) than it is at pH 12.0. In other words, the adsorptive activity is actually four times greater at the intestinal pH than it at pH of 12.0 that we used in the determinations shown in Table I because it was more convenient for our work. Thus *5 gms. of activated charcoal (N) might be considered a complete adsorbent for 1 gm. of phenolphthalein,* if the time of exposure is 5 minutes and the temperature 25° C. at the pH of 8.0.

Our findings agree in principle with the data of Hauge and Willaman (3) who found that "increasing acidity permits greater adsorption of caramel and of benzoazurin (negatively charged colloids)." These observers also state that alkalinity favors adsorption of electropositive substances, such as methylene blue: while adsorption of non-electrolyte substances is unaffected by the pH ion concentration.

TIME AND TEMPERATURE

It is self evident that variations in time and temperature will alter the results as far as adsorption by charcoal is concerned. Inasmuch as in the system we are interested in, the gastrointestinal tract, a higher temperature and longer time of exposure prevail than those we employed in our test-tube experiments, determinations were made to find to what degree the adsorption of phenolphthalein was changed by increase in time and temperature.

It will be seen from Graph 4 that increase in time of exposure progressively increases the percentage ad-

Graph I

sorbed, so that after sixty minutes there is a 30% greater adsorption than at the five-minute exposure.

Increase in temperature also increases the percentage adsorbed and it does so by about 20% at any length of time exposure.

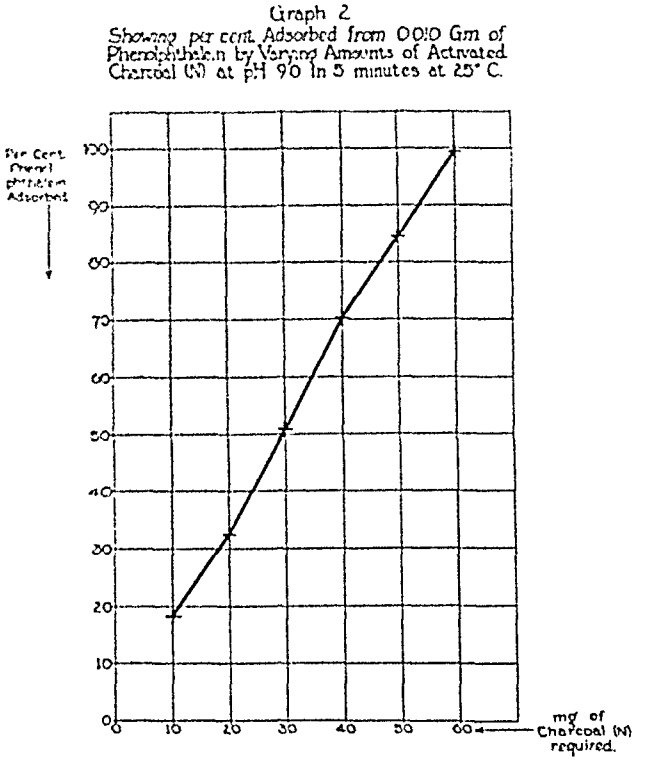
DISCUSSION OF TEST TUBE EXPERIMENTS

We have found that it required 5 gms. of the best *quality of activated charcoal* (N) to absorb 1 gm. of phenolphthalein at 5 minutes exposure and the temperature at 25° C. As will be noted from Graph 1, the various charcoals that meet the U. S. P. requirements cluster fairly closely together, with the least active being about 20% below the most active. Inasmuch as time and temperature both increase the adsorptive capacity of charcoal by 30% and 20% respectively, we may consider these influences to be adequate to neutralize differences in adsorptive power of various official activated charcoals.

PHENOLPHTHALEIN WITH CHARCOAL IN THE CAT

We have found that, when cats are fed 2% or 4% of phenolphthalein in their daily food ("Kitty Ration" and skimmed milk), it generally is without cathartic action; but that 8% of phenolphthalein in the cat's food usually has a laxative effect. This latter dose is somewhat less than 3 gms. per kg. of the cat's body weight.

By increasing the dose of phenolphthalein to 3 gms. per kg. and giving this by stomach tube, just before the day's food was offered, we secured laxative action in 7 out of 8 instances, as shown by Table III, Part A. The probable explanation for the lack of action, on March 24, in cat No. 13, may be found in the fact that, for some reason or other, the phenolphthalein had formed a hard lump, which was attached to but separate from the stool. This cat No. 13 had a definite laxative effect from the same dose on March 17, a week earlier. Taking the results as they stand, we can report that this dose was laxative in 84% of the observed cases, although the probabilities are that, had the lump formation been prevented, we would have obtained a 100% result.



By giving this practically certain cathartic dose of 3 gms. of phenolphthalein per kg. of the cat's body weight mixed with 15 gms. per kg. of Activated Charcoal, we secured results tabulated in Part B of Table III. It will be seen, from this tabulation, that there was no laxative action excepting in one case (Cat No. 2) on March 17; and that, in this cat, the laxative effect was much delayed. A week later, March 24, Cat No. 2 had no laxative effect from the same combination. Summarizing the results as they stand, we may conclude that the charcoal inhibited the laxative effect in at least 84% of the cases.

It is obvious therefore, from this study, that activated charcoal does prevent or much delay the laxative action of phenolphthalein in these cat experiments.

To determine whether the adsorptive activity of charcoal was used up by its passage through the alimentary tract, stool specimens from these cats were studied for their ability to adsorb phenolphthalein. Adsorptive activity was found in only one stool which was passed five hours after the taking of the phenolphthalein. All other stools were obtained 24 or more hours after taking the charcoal and these no longer had any adsorptive power.

PHENOLPHTHALEIN AND CHARCOAL IN THE HUMAN

To determine whether these findings apply to the human, one of us took, on March 17, a dose of 0.30 Gm.

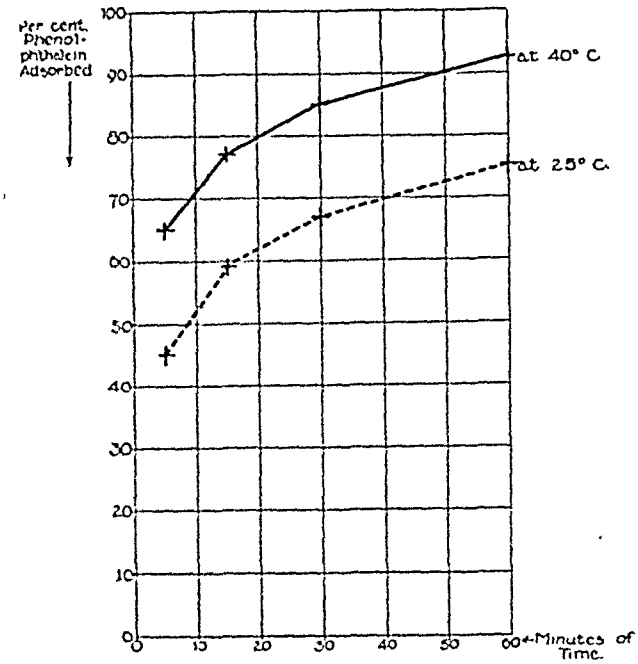
of phenolphthalein in capsule and followed this immediately by five times this quantity (1.5 Gm.) of charcoal (M). This combined dose produced a definite laxative effect lasting two days. Even so, as a dose of 0.12 Gm. always has a more powerful action than was secured from the larger dose with charcoal, the impression cannot be dismissed that a certain degree of inhibitory action was secured. It seems, however, that the 1 to 5 relation of the phenolphthalein to charcoal does not apply to the human. This probably is due to the fact that the total quantity of charcoal taken by the human is very much smaller than that taken by the cat and that most of the enormous dose of phenolphthalein given to the cats does not get into solution at all, owing to the poor solvent powers of their intestinal juices. We, therefore, proceeded to test this hypothesis by administering a liberal excess of activated charcoal, which was done in the following experiment:



March 26, 1936, 11:30 a. m. Dose: 0.3 Gm. phenolphthalein followed by 5 gms. of Activated Charcoal (M) every two hours until 10:30 p. m. and another

Graph 3

such dose at 8:00 a. m. next day. There was no laxative action the next day or the day thereafter.

CONCLUSIONS

1. Activated Charcoal of U. S. P. XI is a definite adsorbent for phenolphthalein, while Non-Activated Charcoal is almost devoid of this effect.
2. The adsorptive power of the charcoal is increased by diminution in degree of alkalinity, by increase in temperature and in the time of exposure.
3. Activated charcoal is capable of antagonizing the cathartic action of phenolphthalein in the cat when given in five times the dose necessary to produce the laxative action.
4. In the human, a considerably larger excess of activated charcoal is required; but, when such is given, the cathartic action is inhibited.

It seems probable that this new official preparation (Carbo Activatus) will be found much more effective than the formerly official form for various therapeutic purposes and that it may reinstate charcoal in the favor and confidence of the discriminating physician. Renewed studies of the therapeutic value of the new charcoal are decidedly in order.

SECTION VII—*Surgery of the Lower Colon and Rectum*

Superior Peri-Rectal Abscesses*

By

J. HALL ALLEN, A.B., M.D.
PHILADELPHIA, PENNSYLVANIA

A BRIEF review of the anatomy of the superior peri-rectal space will help us to obtain a clear conception of the etiology and pathology of inflammations in this area.

The rectum passes through this space from above downward; the space is bounded by the pelvic peritoneum above and the levator ani below; the rectum in this space is surrounded by a fibro cellular layer of tissue through which ramify the arteries, veins and nerves before they penetrate the walls of the bowel.

*From the Department of Proctology, Jefferson Hospital.
Submitted February 26, 1936.

This space is subdivided into the posterior or the retro-rectal space and two lateral spaces anterior to the rectum known as the superior pelvi-rectal spaces. The blood vessels in the retro-rectal space are branches from the middle and lateral sacral arteries also a few from the inferior mesenteric. Those in the superior pelvi-rectal spaces come from the hypogastric artery. The lymphatics of the two spaces are also comparatively distinct: those in the retro-rectal space develop around the lower posterior portions of the rectum and coccyx, while those in the anterior spaces originate in the wall around the prostate, neck of the bladder and the uterine organs and connect with the iliac plexus and lateral trunks of the lymphatic system.

With such distinct anatomical divisions, vascular supply and lymphatic distribution, one can clearly understand why a distinction is made between the circumscribed inflammations in these two areas and distinguish them as retro-rectal and superior pelvi-rectal abscesses.

The retro-rectal abscess develops in the space between the sacrum and the rectum. It may be due to necrosis of the pelvis, sacrum, coccyx, ileum or vertebrae, to a foreign body in the bowel or the passage of bougies and hard rubber syringe tips. The operation of posterior proctotomy where complete drainage is not secured, is a frequent cause.

Strictures and fistulous tracts of the rectum, gummata, tuberculous lymphoid nodules and infection carried along the lymphatic channels from ulceration of the rectum above the external sphincter are other causes.

SYMPTOMATOLOGY

The early symptoms are vague and obscure. Usually they are not ushered in by a distinct chill. A dull ache in the sacral area with pains along the course of the sciatic nerve, malaise and constipation, with or without pain on defecation. Seen early, palpation externally around the perineum, as a rule does not elicit any pain or induration, there will be no fluctuation or tension. As suppuration increases, palpation with the gloved finger in the rectum will at times reveal marked pain, enlarged lymphatic glands a small abscess bulging into the lumen of the bowel or a diffuse boggy mass in the hollow of the sacrum, accompanied by a marked increase in temperature at this point.

The bowel may be partially obstructed and difficulty in micturition will develop. A blood count with an increased leucocytosis and an increase in the polymorphonuclears will be confirmative evidence of an abscess.

An X-ray film, where the cause is a bone lesion, will aid in the diagnosis.

Eventually an abscess may rupture spontaneously into the rectal cavity; it may also perforate the levator ani into the ischiorectal fossae and finally open through the skin.

TREATMENT

Such consists in drainage as early as possible to prevent rupture into the bowel. A slightly curved incision between anus and coccyx is best. This should reach to the levator muscle. With the index finger in the rectum as a guide, a bistoury is then passed with the cutting edge away from the bowel, through the levator muscle cutting at right angles to its fibres to facilitate free drainage. The remainder of the dissection is best done with the finger, increasing the size of the opening in the muscle and evacuating the cavity.

Curetting is not generally advisable on account of the possibility of perforating the superior pelvi-rectal spaces or rectum. A large size rubber drainage tube is introduced and held in position by a suture or adhesive strip at the skin margin. The sphincter should be stretched and the bowels kept regular, but not loose during convalescence. The wound should be irrigated through the tube twice daily for the first week with a glass syringe, using 1-2000 bichloride solution, a 1-2000 metaphen solution or a 2 per cent amphyl solution. No packing used after the first dressing at time of operation. As soon as possible get the patients on their feet for a short period daily, this facilitates drainage by gravity and by pressure of the abdominal contents above. Sitting should not be allowed until healing is well advanced.

Where the abscess has ruptured into the bowel previous to the patient being brought to operation; the function of the bowel will be best preserved by using the so called *seton*. This may be a silk or rubber band. It is inserted through the outside dissection and through the internal opening into the bowel, brought down and out through the external sphincter muscle and tied.

The tension of this *seton* is so regulated that it cuts slowly through the tissues from above downwards allowing the healing to keep pace with the cutting.

This procedure will usually require from four to six weeks, depending upon the patient's general health.

SUPERIOR PELVI-RECTAL ABSCESSES

These usually do not have their origin primarily from inflammation of the rectum but from surrounding organs, as the bladder, prostate, urethra, uterus, broad ligaments. Psoas abscess, necrosis of the pelvic bones, suppuration of the broad ligament, vesiculitis, perinephritis, and appendicitis may all cause an abscess in the superior pelvi-rectal spaces. Injuries in the anterior wall of the rectum, traumatism from labor, instrumentation of the urethra or uterus, operations for removal of stones in the bladder, prostatectomy and uterine tumors have all been known to cause these abscesses.

The chief causes however are infections of the prostate, seminal vesicles, uterus and broad ligiments. They usually begin with chill, fever, increased pulse rate, deep aching pain and urinary disturbance. Occasionally they develop slowly with very slight chill and slight fever.

Where the inflammation is tuberculous the symptoms will be less marked and the progress slower. In gonorrheal infections, the temperature may become very high and the constitutional symptoms alarming. The abscesses have a tendency to burrow outward toward the abdominal wall because of there being less resistance in this area than toward the perineum. A localized peritonitis may occur or they may perforate the peritoneum and death occur from acute septic peritonitis.

Perforation of other organs, bladder or rectum may also occur during the course. A sudden discharge of much pus through the bladder or rectum with relief

of pain and distress would indicate this; perforation of the vagina is rare.

A *diagnosis* of superior pelvi-rectal abscess rests largely upon diseases of the genito urinary and reproductive organs; rarely is there a history of previous rectal disease. Peri-anal or perineal palpation elicits deep tenderness but no swelling or induration. Rectal palpation will generally reveal a tenderness above and to one side of the prostate in the male; when the abscess has existed for some time it may become quite tense and burrow downward between the rectum and the prostate, perforate the levator ani muscle or penetrate the retro-rectal space.

It is in the early period of this inflammation that one finds it difficult to make an exact diagnosis and an early diagnosis is important in view of the grave complications which may arise from delay. The urinary symptoms often mask the rectal symptoms in men. In women these symptoms are generally taken to indicate an inflammatory condition of the uterine organs and a vaginal examination is soon made revealing the true nature of the inflammation.

In men as a rule these abscesses are situated anterior to and to one side of the rectum, they may be on a level with the prostate or just above it. In women they are more likely to be found to one side than anteriorly because the pelvi-rectal spaces are separated in front by the close union between the rectum and the vaginal wall below, and also because the lymphatics run along the borders of the broad ligament and therefore the infection is distributed along the sides.

These abscesses occasionally surround the rectum and destroy all the cellular tissue between the peritoneum and levator ani. They may perforate the levator ani and enter the ischiorectal fossa or the retro-rectal space. Those perforating into the ischiorectal fossa may later open through the skin in the anal region.

In cases where there has been much destruction of tissue around the rectum, there is not much prospect of restoration of perfect function of these parts. In the early stages it may be nearly impossible to diagnose these abscesses, though the general symptoms may indicate pus formation.

A blood count with marked leucocytosis would strengthen the indication of a developing abscess. Sigmoidoscopic examination or passage of rubber bougies would be contra-indicated on account of the danger of rupturing the abscess into the rectum.

TREATMENT

This consists in evacuating the abscess at the earliest possible moment and affording wide free drainage. The abscess should be opened by a deep dissection through the perineum. It is rarely justifiable to open it through the rectum, as it usually further complicates a serious condition. When the abscess cavity has been reached by the dissection, the use of the finger in blunt dissection is advised; there will be less injury of the large blood vessels and nerves and less possibility of rupture into the peritoneal cavity. A large rubber drainage tube is then inserted and fixed to the skin margin. The cavity should be thoroughly evacuated by irrigation with normal salt solution. The sphincter muscle should always be divulsed so that gas and fecal matter can pass easily, avoiding any additional strain to the weakened tissues separating the abscess from the rectum. If the urethra or bladder has been perforated by the abscess the conversion of the abscess into a perineal-urinary fistula will be the safest and surest means of securing a cure. In the after treatment rubber drainage tubes are preferable to gauze. No packing is used; after forty-eight hours a smaller tube may be inserted; this should gradually be shortened and removed entirely when the cavity has been sterilized. For irrigation a 1-5000 solution of bichloride of mercury, a 1-2000 solution of mercurophen or a two per cent solution of amphyl may be used. Irrigate two to three times a day for the first week, gradually reducing the frequency as the cavity clears. Get the patient on his feet as soon as possible to favor drainage.

CASE REPORT

The following history will illustrate the superior pelvi-rectal variety of abscess: A. C., age 53, a fisherman, Swedish ancestry, began having pain three weeks previous to time when first seen. He had consulted a surgeon who diagnosed and operated upon a superficial fistula in ano. At that time an enlarged prostate was diagnosed which was giving marked urinary symptoms. The day following the fistula operation, the patient complained the pain for which he had entered the hospital had not been relieved, became dissatisfied, signed a release and went home.

I saw him five days later when he had developed a retro-rectal abscess which protruded into the lumen of the bowel. The prostate was enlarged and firm and tender on palpation. No fluctuation noted. He was removed to the hospital on same day. On proceeding to drain the abscess it was found it had ruptured. It was drained by an external incision between the anus and coccyx, drainage tube inserted and he felt much but not entirely relieved. A polyvalent serum was then started to promote more rapid healing of the cavity.

Six days later he developed a pain in inguinal region and testicles; this was followed by a rise in temperature and painful area in right iliac fossa. Two days later there was a profuse discharge of pus through the drainage opening of the retro-rectal abscess. Under gas anesthesia it was found a prostatic abscess had ruptured through the superior pelvi-rectal space and into the drainage tract of the retro-rectal abscess. This was opened by blunt dissection, a rubber drainage tube inserted. A prompt cessation of all prostatic symptoms followed, and an excellent result was obtained.

Elbow Deformity of the Colon*

By

JEROME MORLEY LYNCH, F.A.C.S., M.D.

and

G. JOHNSON HAMILTON, M.R.C.S., M.D.

NEW YORK, NEW YORK

ELBOW deformity of the colon may be described as a V-shaped angulation, formed by the close approximation of the cecum to the hepatic flexure, with no diminution of the usual length of the ascending colon.

The origin of the condition is primarily a developmental arrest. The caecum, ordinarily, reaches its final position in the right iliac fossa by passing through two stages. It makes its appearance about the third week of foetal life, outside the body cavity. During the seventh week, it is drawn into the coelum and undergoes rotation to place itself over the right kidney. Thence, it grows downwards into the right iliac fossa. Subsequently, when all the abdominal viscera have achieved their normal habitats, a physiological peritonitis occurs. This results in the formation of adhesions whereby portions of the colon are fixed. Surgically, this is of the greatest importance, since by separating the adhesions, any fixed portion of the gut may be mobilized with its mesentery.

This high position of the caecum possesses advantages and disadvantages. The advantages are that the arrest in position corresponds with a halt in the development of the caecum which tends to remain small. This in turn obviates that form of constipation and its toxic concomitants which are associated with an overdeveloped caecum.

The disadvantages of the position are that the long loop of gut, suspended on a mesentery with a short base, is peculiarly susceptible to accident. The most common one is obstruction of the ascending colon, which is usually partial, but may be complete. The cause may be acute angulation, torsion, or obstruction by a band.

SYMPTOMATOLOGY

The most common symptoms of the condition in their approximate order of frequency are:

1. *Constipation,* pain and auto-intoxication.

These symptoms are produced by a delay in the fecal movement through the ascending colon. This is a mechanical effect of the acute angulation described as elbow deformity. The delay may range from a slight halt to a complete obstruction and the symptoms are commensurate with it. The pain is due to the drag of the loaded colon upon its mesentery.

2. *Regular epigastric pain and vomiting.*

Peptic ulcers are frequently simulated by this condition. The origin of the symptoms is a narrowing of the lumen of the duodenum or distal portion of the stomach. This may be the mechanical result of an adhesion between these viscera and the ascending colon or may be a reflex spasm from the same cause. Obviously, this may be a very difficult condition to diagnose. The delay in emptying time of the stomach with accompanying change in the gastric chemistry, distortion of the duodenal cap, etc., all point to some change in the lumen, and the erroneous conclusion that the change is either within the lumen or within the wall of the gut, rather than a force acting outside the wall.

If the condition is suspected, an opaque enema usually confirms the diagnosis.

3. *Back-ache, fatigue,* pain resembling Deitl's crisis, or stone in the ureter.

These symptoms are caused by adhesions over the kidney or ureter. The resultant tension may be slight and constant or strong and periodic. In this position, the adhesions are over the ilio-hypogastric and ilio-inguinal nerves and reflex manifestations may appear throughout their course. Common among these are frequency of micturition and pain in the anterior part of the perineum. Sharp spasms may be due to torsion of the pedicle.

4. *Flatulent dyspepsia,* sub-costal pain, pruritus and frank jaundice.

These symptoms are due to involvement of the gall bladder or biliary ducts in adhesions to the ascending colon. Again, the diagnosis is rendered difficult, since the most common causes of these conditions are mechanical obstruction within the lumen or malignancy without. Skiagrams are not of positive assistance but may yield negative information of value.

Very commonly, one or other of these syndromes exists in such a mild degree that the busy practitioner is unable to make a clinical diagnosis and is loathe to expend large sums of the patient's money upon chemical and radiological investigations. Frequently, the cases are labelled chronic appendicitis and referred to a surgeon. For various reasons, the appendectomy is often performed through a niggardly incision, no exploration is made, the condition is unrecognized, and the symptoms persist. The cost of an opaque enema is slight and it usually affords a rapid diagnosis. The disadvantages of an incision suitable for exploration are usually negligible.

Treatment of the condition is, of course, surgical. The technique utilizes a laparotomy incision, through which a thorough exploration is made. All adhesions are freed. The outside leaf of the mesentery of the caecum and ascending colon is opened throughout its length. Its contents are gently spread out. The caecum

*From Lynch Clinic, New York, N. Y.
Submitted April 23, 1936.

Fig. 1. Elbow deformity with post-caecal appendix and transverse band from caeco-sigmoid to mesentery.

and ascending colon are sutured into their proper position and so obliterate the slit in the mesentery.

CASE REPORTS

Histories of patients with these syndromes are appended and it is noteworthy that in this brief series there are two cases in which a previous appendectomy had failed to relieve the symptoms. The grouping has been made according to the prevailing symptoms, rather than the actual diagnosis.

Case No. 3821

1. *Mr. F. G.*, age 23. Salesman.

Symptoms—One year.

Family history—Mother died of cancer.

Past history—No serious illness.

Present history—Pain in right side, constipation.

Urinary history—Negative.

Physical examination—Some tenderness in right lower quadrant. Otherwise negative.

X-ray—Chronic appendicitis.

Pre-operative diagnosis—Same.

Findings—Chronic appendicitis, long and tortuous. Elbow deformity of colon.

Operation—Plication of caecum and appendicostomy (July 10, 1934).

Case No. 4402

2. *Mr. H. B.*, age 34.

Family history—Negative.

Past history—Typhoid fever at 10 years.

Present history—Pain in the right side in region of appendix for five weeks. Sharp pain at first, dull pain last two weeks. No vomiting.

Pre-operative diagnosis—Elbow deformity and chronic appendicitis.

Postoperative diagnosis—Same.

Findings—The appendix was running parallel to and adhered in one place to the right border of the liver. The ascending colon was undescended and there was no caecum. The ascending colon was turned in horseshoe form, the opening being toward the anterior abdominal wall.

Operation—Plication of caecum and appendectomy (March 13, 1925).

Case No. 4477

3. *Miss K. S.*, age 24. Law Student.

Past history—Negative.

Present history—For two years had pain in right lower quadrant radiating down thigh, nausea, vomiting and constipated.

Physical examination—Tenderness over McBurney's point and palpable caecum.

X-ray—Chronic appendicitis and bands across ascending colon and transverse colon causing partial obstruction and tremendous dilatation of colon and caecum.

Pre-operative diagnosis—Elbow deformity and chronic appendicitis.

Postoperative diagnosis—Same.

Findings—Acute angulation due to bands and chronic appendicitis.

Operation—Plication and appendectomy (1925).

Case No. 3973

4. *Miss R. D.*, age 29.

Past history—Negative.

Present history—Epigastric pain, no vomiting. Some nausea, eructation, appetite—poor, constipated. Stools—normal. Lost 30 pounds in six months. Some night sweats.

Physical examination—Caecum palpable and tenderness over McBurney's point.

X-ray—Inflammation of caecum and colon, possible tuberculosis.

Pre-operative diagnosis—Tuberculosis of ileum and caecum.

Postoperative diagnosis—Elbow deformity.

Findings—Marked elbow deformity of the ascending colon and long appendix. Cyst of left ovary.

Operation—Appendectomy and plication of caecum.

Case No. 2988

5. *Mr. E. M.*, age 35.

Past history—Negative.

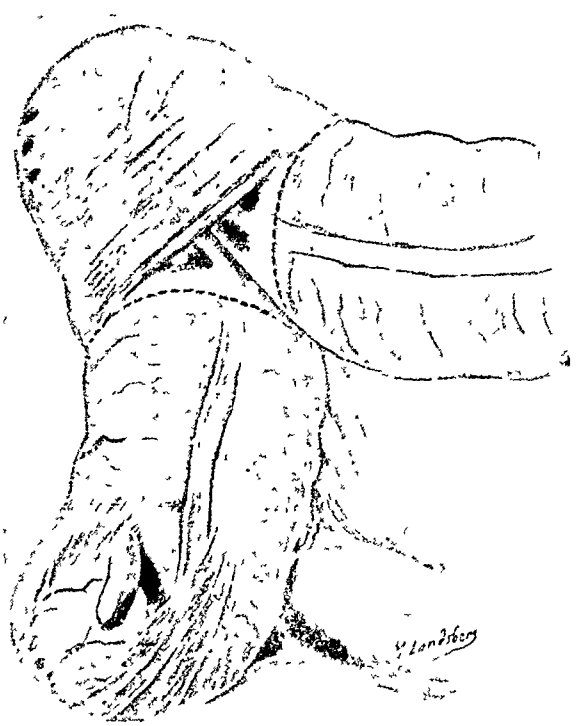

Fig. 2. Elbow deformity with cuff inclusion and post-caecal appendix.

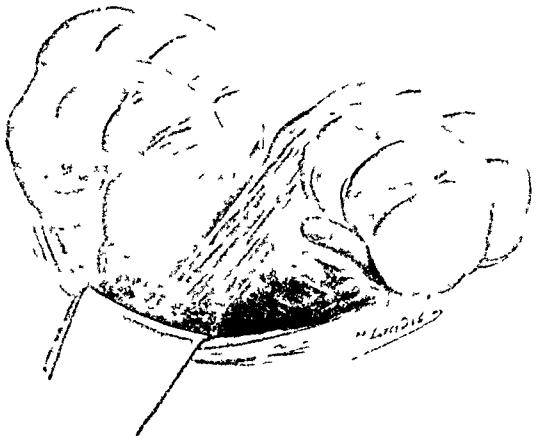

Fig. 3. Elbow deformity with lateral band from caecosigmoid to mesentery and post-caecal appendix.

Present history—Gastric pain relieved by food. No vomiting. Some eructations. Constipated.
X-ray—Chronic appendicitis.
Physical examination—Tenderness in right iliac fossa referred to epigastrium.
Pre-operative diagnosis—Elbow deformity and peptic ulcer.
Postoperative diagnosis—Elbow deformity and chronic appendicitis.
Findings—Elbow deformity and chronic appendicitis with adhesions to anterior wall.
Operation—Plication and appendectomy.

Case No. 4223

6. *Mr. W. C.*, age 23.
Past history—Negative.
Present history—Epigastric pain, vomiting and diarrhea relieved by vomiting. Intermittent attacks for five years. Flatulence marked.
X-ray—Duodenal ulcer.
Pre-operative diagnosis—Duodenal ulcer and elbow deformity.
Postoperative diagnosis—Chronic appendicitis and elbow deformity.
Findings—Adhesions to stomach, gall bladder, pylorus, caecum and colon. Base of infantile appendix adherent to gall bladder.
Operation—Freeing of adhesions, appendectomy, resection of 3 inches of ascending colon (1925).

Case No. 4215

7. *Mr. G. W.*, age 31.
Past history—Negative.
Present history—Bouts of epigastric pain relieved by food for 8 years. No nausea, no vomiting, constipated.
X-ray—Negative.
Pre-operative diagnosis—Duodenal ulcer, chronic appendicitis and adhesions.
Postoperative diagnosis—Elbow deformity, adhesions and chronic appendicitis.
Findings—Colon adherent to gall bladder, pylorus and omentum. Elbow deformity.
Operation—Adhesions freed, appendectomy, and plication of caecum (1925).

Case No. 4259

8. *Miss M. C.*, age 26.
Past history—negative.
Present history—Epigastric pain relieved by food. Vomiting. Pain 2 hours after food. Flatulent.
Physical examination—Tenderness over right lower quadrant.
X-ray—Chronic appendicitis and adhesions.
Pre-operative diagnosis—Elbow deformity and chronic appendicitis.
Postoperative diagnosis—Same.
Findings—Ascending colon adherent to liver. Elbow deformity.
Operation—Plication of caecum. Appendectomy and freeing of adhesions. A portion of liver was removed.

Case No. 595

9. *Mrs. M. H.*, age 26. Nurse.
Family history—Negative.
Past history—Measles, scarlet fever, typhoid fever, rheumatism, diphtheria, pneumonia and appendectomy.
Urinary history—Micturition 1-3 times daily.
Present history—Pains, onset in back, radiating to right groin, intermittent fever, colicky attack lasted 15 minutes. Bloody urine, not constipated, vomited on this attack. Has had attacks before but no severe pain. Urinary history at times every hour daily.
Cystoscopic examination—Negative. Dr. J. Bently Squier ruled out urinary pathology.
Pre-operative diagnosis—Elbow deformity of the colon.
Postoperative diagnosis—Same.
Findings—On opening the abdomen, a very large, dilated, non-fused caecum appeared in the wound. The right kidney was examined and found contracted. There was also slight constriction of the lower pole of the right kidney but the left kidney was somewhat larger than the right. All organs were found normal except for a *marked elbow deformity of the colon.*
Operation—Plication of the caecum by Dr. Lynch, October 22, 1920. All symptoms cleared up within 12 days.

Case No. 4226

10. *Mrs. R. S.*, age 32. Housewife.
Symptoms—One year.
Family history—Negative.
Past history—No serious illness. Previously operated upon for removal of uterus, left ovary and appendix.
Present history—Pain in right iliac fossa. Pain, sharp, radiates to back. Constipation severe. Pain has no relation to food. No nausea or vomiting.
Urinary history—Slight frequency of urination during attacks.
Physical examination—Tenderness in right iliac fossa. Palpable caecum. Moveable right kidney.
X-ray—No abnormality of urinary tract.
Pre-operative diagnosis—Cystic right ovary and elbow deformity.
Postoperative diagnosis—Same.
Findings—Cystic right ovary and dilated flappy caecum, also one band of adhesions causing elbow deformity of ascending colon. Stomach and gall bladder—normal.
Operation—Punctured ovarian cyst and plicated cecum (Jan. 13, 1925).

Fig. 4. Elbow deformity showing funnel-shaped embryonic caecum.

Case No. 4314

11. *Miss C. H.*, age 26. Telephone operator.

Symptoms—One year.

Family history—Father died of cancer.

Past history—No serious illness.

Present history—Pain in R. L. Q. during menstrual periods for 1 year but for the past week pain was between periods and accompanied by vomiting. Bowels constipated.

Urinary history—Burning and pain for last week.

Physical examination—Negative except for some tenderness over McBurney's point.

Pre-operative diagnosis—Subacute appendicitis.

Postoperative diagnosis—Chronic appendicitis, elbow deformity and non-fused colon.

Findings—Long appendix, adhered to lateral colic fold. Non-fusion of colon with common mesentery. Gall bladder and stomach—normal. Small cysts of both ovaries.

Operations—Appendectomy and plication of caecum (Sir Henry Gray technique (Feb. 10, 1925).

Case No. 4131

12. *Miss T. M.*, age 26.

Symptoms—2 years.

Family history—No chronic diseases.

Past history—No serious illness.

Present history—For past 2 years pains and burning in the stomach. Nauseated, sour stomach, no vomiting. Headaches. Belches a great deal. Lost 15 lbs. in weight. Constipated. Pains relieved at times by food.

Urinary history—Frequent desire for urination of late.

Physical examination—Negative except for tenderness over epigastrium and R. U. Q.

X-ray report—Moderate ptosis of stomach and small intestines.

Pre-operative diagnosis—Elbow deformity, chronic appendicitis and adhesions.

Postoperative diagnosis—Same, cholecystitis.

Findings—Chronic appendicitis and chronic cholecystitis and elbow deformity of colon. Gall bladder looked ashy gray and when cut open had typical strawberry appearance of chronic inflammation. The caecum was pigmented. Stomach normal, duodenum dilated because of elbow deformity of colon.

Operation—Cholecystectomy and appendectomy and plication of caecum.

Case No. 4276

13. *Mrs. C. C.*, age 50.

Symptoms—Constipated all her life.

Family history—Father died of Bright's disease; mother died of apoplexy.

Past history—No serious illness.

Present history—Constipated and troubled with indigestion all her life. Three years ago severe attacks of pains in R. U. Q. Pains radiated to the back in both sides of the spine. Vomitus—green. Slight fever, became jaundiced 3 days later. Similar attacks 3 or 4 months but no jaundice. Constant pain for past 5 weeks. Passes a good deal of mucus by bowels, stools never clay colored.

Physical examination—Negative except for tenderness over McBurney's point and gall bladder region.

Urinary history—Negative.

X-ray—

Pre-operative diagnosis—Chronic appendicitis and chronic cholecystitis.

Postoperative diagnosis—Elbow deformity, chronic appendicitis and adhesions.

Findings—Dense adhesions about gall bladder—adhesions binding caecum to parietal peritoneal wall near hepatic flexure of colon. One strong band of adhesions from anterior longitudinal band near caecum to hepatic flexure of colon. Another band of adhesions from ascending colon to gall bladder. The caecum was of the flappy, dilated type. The stomach and sigmoid appeared normal. Small chronically inflamed appendix.

Operation—Freeing adhesions, appendectomy and plication of caecum.

Case No. 4225

14. *Mrs. E. R.*, age 36. Clerk.

Past history—Negative.

Present history—Pain in the stomach about 2 hours after going to bed, wakes her up. Steady pain. Belches. Forced vomiting, which relieves her. Brown fluid. Bowels constipated. Cascara every night. Feels like eating but is afraid to eat meats, etc.

Urinary history—Negative.

Physical examination—Negative except for tenderness over the descending colon.

X-ray examination—Shows the presence of a partial obstruction in the upper half of the second portion of the duodenum, apparently due to adhesions between the gall bladder and the adjacent viscera. The rest of the second portion of the duodenum was slightly dilated and there was a moderately delayed motility there. The appendix, too, was apparently chronically inflamed with apparently ileocecal adhesions.

Pre-operative diagnosis—Chronic cholecystitis, chronic appendicitis, adhesions and elbow deformity.

Postoperative diagnosis—Elbow deformity, chronic appendicitis, attic adhesions and small multiple fibroid uteri.

Findings—Chronic appendicitis, flappy, dilated caecum and elbow deformity of ascending colon. Few fine adhesions around duodenum. Uterus had several small fibroids.

Operation—Freeing adhesions, appendectomy and plication of caecum.

Annual Abstracts of Proctologic Literature

(May, 1934-May, 1935) By CLEMENT L. MARTIN, M.D., Chicago, Illinois

The complete bibliography from which these Abstracts were made will be published in full in the Transactions of the American Proctologic Society, 1935.

LYMPHOGRANULOMA INGUINALE

For a brief description of this disease see Transactions 1933-1934, more detailed ones will be found in Hellerstrom's monograph, in *Cole's* paper, *J. A. M. A.*, 101:1069 (Sept. 30), 1933, and *Fischl's* article and others cited in this and previous bibliographies.

Synonyms: Lymphopathia venerea, *Nicolas-Favre-Durand* disease, climatic bubo, tropical bubo, hypertrophic bubo, non-venereal bubo, strumous bubo of the groin, subacute inguinal paradenitis, "fourth" venereal disease, non-tuberculous granulomatous lymphadenitis, subacute inguinal lymphadenitis; some, perhaps most of the cases of "hypertrophic and stensosing rectitis" described by the French, some of the cases of genito-anorectal elephantiasis, some, if not nearly all, cases of "esthiomene." It may be noted that ulcus vulvae acutum (Lipschutz) is a separate entity as is *"periadenitis mucosa necrotica recurrens."* O'Leary criticizes the use of the latter term; he regards it as synonymous with ulcerating aphthous stomatitis, a local disease, and classifies those cases with both vulvar and

mouth lesions as "ulcerative vulvitis and stomatitis, a systemic (disease)."

ETIOLOGY

There are few noteworthy additions to our knowledge of this disease to report this year. That the disease is a definite entity and the Frei test is specific have been established in the past; various current articles confirm this. That the disease is caused by a filtrable virus is generally but not universally accepted. Levaditi, Ravaut, *et al*, determined that the serum of patients with the disease neutralizes lymphogranuloma inguinale virus *in vitro*. Grace and Suskind succeeded by intracerebral inoculations of mice in transmitting the virus through 35 generations (sub-inoculations), with marked increase of its virulence and thus prepared an active mouse-brain antigen. The Reviewer has found it more potent than most of the antigens prepared from suppurating inguinal glands, but it may give false positive reactions.

THERAPY

There would be a clearer concept of therapeutic possibilities in the proctologists field if certain facts emphasized by Collier Martin, among others, generally were known and appreciated. Dr. Martin notes that it is chiefly a Negro disease, best described as "incurable" thus far; that it expresses itself as a rectal stricture in the female, and that its prominent feature in the male is an inguinal adenitis following a primary sore on the penis, the adenitis frequently suppurating. Fifteen of his cases . . . . "all had massive peri-rectal deposits of inflammatory tissue with marked contraction of the lumen of the bowel and multiple rectal and peri-rectal infections with fistulas involving the peri-anal area."

It is hardly to be expected that most of the medicinal agents used and advocated for this disease could exert much effect on the tubular strictures and dense scar tissue we find in these patients. Dilatation with bougies, cautiously done, posterior linear proctotomy and, in the more advanced cases, colostomy, have definite value in the treatment of the rectal stricture.

Conservative surgical measures, *i.e.*, incision and drainage of peri-anal abscesses and curettage or the swabbing out of sinuses which may be readily explored, is helpful in some cases. The Reviewer does not hesitate to perform a fistulectomy on these patients if the internal orifice is at the muco-cutaneous juncture; they are benefited and the wound heals. Fistulectomy is indicated only in the exceptional case, however. Antimony and potassium tartrate continues to have advocates: 5 c.c. of a 1% solution given intravenously twice a week is the usual dose. Rainey gives 3 c.c. for the first dose and increases this up to 7 c.c. on the 5th dose if it is well tolerated, dosage is then maintained at 7 c.c. Intradermal injections of 0.1 c.c. of antigen twice a week, as advocated by Pilot, are being given in a number of cases. It is still too early to determine their value, but my own results are not encouraging.

My experience with any medication in this disease has not been encouraging. For the inguinal adenitis, roentgenotherapy is used by some authors; after suppuration occurs, simple incision, curettage or gland excision is variously practised. Weeks advocates radical excision of enlarged and suppurating glands. Hot moist dressings are then commonly applied.

Thomas and McCarthy report favorably on the use of a bouillon filtrate applied as a wet dressing to the suppurating glands.

MEGACOLON

Bonar designates as "pelvi-rectal achalasia" that type of Hirschsprung's disease apparently caused by failure of relaxation of the musculature at the pelvi-rectal flexure. A case is reported of a boy 3 years of age with this dysfunction who was treated by repeated intrarectal injections, of a saturated solution of magnesium sulphate. In the course of two years over 200 satisfactory bowel movements were obtained, abdominal distention was reduced, and nutrition and health were decidedly improved. While surgical division of the sympathetic nerve supply to the large bowel is the treatment of choice, Bonar suggests that the age and condition of the patient often makes preliminary medical treatment necessary, and, the procedure described may be a valuable adjunct, if his results are confirmed.

NEOPLASMS

The relation of polyps to rectal cancer continues to be investigated. The most careful and worthy work in the last year with which I am familiar is that of *H. Westhues*. His book 'The Pathologico-anatomical Basis of Surgery for Rectal Carcinoma" is reviewed in the December issue of the American Journal of Digestive Diseases and Nutrition. Although I do not fully agree with his classification of polyps, his material is different from my own and his findings are supported by much data.

Bargen and Dixon report on uncommon tumors in the large intestine. They found reported in the literature fibroma, fibromyoma, fibromyxoma, fibromyxangioma, adenofibromyoma, fibroleiomyoma, myoma, adenomyoma, angioma, lipoma, cholesteotoma, paraffinoma, taratoma, glioma, dermoids, and cysts. They report a case of fibroma in the cecum and one of myosarcoma of the rectum. They advise surgical treatment in all these conditions.

Coccyxgeal dermoids are discussed by *Ferrari and Meyer-Burgdorff*. *Fletcher, Woltman and Adson* present a study of sacrococcyxgeal chordomas.

In his paper on rectal polyps *David* makes the points that a biopsy specimen from the base of the tumor is necessary, that the slightest evidence of ulceration or induration are suggestive of malignancy, and that the pathologist must have a history and definite idea of the tumor's gross appearance and the proper section for a diagnosis.

Newton Smith concludes that rectal polyps are comparatively rare in infancy. When they do occur they seem to grow rapidly and should be removed.

Poston reports an acute intussusception caused by a lipoma in an adult. *McKenney's* paper epitomizes current concepts of colon neoplasms. *Kuru* reports a lymphosarcoma of the rectum. *Read* performed a successful colon resection in a five year old child for a solitary adenomatous polyp which had caused recurrent intussusception. In a case of my own not yet reported, a single adenoma 2 x 2½ cms. was excised from the upper sigmoid by colotomy, recurrent partial obstruction but no intussusception preceded the operation. The child recovered.

Bowman describes a villous papilloma of the rectum with early malignancy, a rare benign tumor which undergoes malignant changes in 12 to 20% of cases. It should be removed when found. It has struck me that these papilloma resemble very closely intravesical papilloma.

OPERATIONS

See titles Prolapse, Sympathectomy, etc., for certain special subjects.

Stetten presented a 38 year old woman with post operative incontinence of 9 months duration who had a satisfactory result after approximation of the separated sphincter ends. The usual procedure was done through a crescentic skin incision.

When incontinence has followed a fistulectomy *Collier Martin* advocates excision of the depressed gutter which extends into or through the anal canal, together with the immediately adjacent scar tissue. Free dissection is avoided. If there has not been too great an interval between the fistulectomy and the operation for incontinence, repair and return of function may result.

Valentine and Rogers report a case of recto-urethral fistula with involvement of the prostate and right seminal vesicle in a 40 year old man who gave a history of repeated catheterizations for urinary retention over a 6 month period when a 5 year old child. At the end of this period

there was a spontaneous discharge of pus through the rectum after which he voided voluntarily. He married at 24 and thereafter had attacks about every three or four years of a feeling of fullness and swelling in the rectum, accompanied by hematuria. At operation the prostate and seminal vesicles were exposed through the usual perineal incision. The space between the rectum, urethra and bladder was occupied by much dense fibrous, inflammatory tissue. This area with "at least a portion of the fistulous tract" was removed and the right lobe of the prostate further incised for drainage. An indwelling catheter was anchored in the bladder and left 7 days. After its removal a little urinary leakage came through the wound for a few days but it then healed firmly. His present condition is satisfactory in all regards.

Johnson describes his technic for repair of complete laceration of the perineum. He states "most textbooks picture the external sphincter muscle as a fat circular band of voluntary muscle fibers . . . (but) actually it can be dissected out, in its major portions, as two elliptical flat muscle bellies about 10 cms. long and 2 cm. wide, with tendinous origins at the ano-coccyxgeal ligaments and tenninous insertions into the central tendon of the perineum; in other words, the main portion of the sphincter ani externus is composed of two independent, almost parallel muscles including the anus between them. The dimple at the sight of the tear is not only scar tissue but the torn fascial and tendinous insertion of the sphincter muscle belly." He approximates the torn sphincter ends by a through and through No. 4 catgut suture embracing skin and muscle, ties this and then stretches the muscle with a rectal dilator. He then removes this suture and does a perinorrhaphy (*Barrett*).

Note that Milligan and Morgan (Anatomy, Transactions, this issue) give a different description of the external sphincter.

Colostomy. Gabriel discusses colostomy based on a study of 970 cases. The chief immediate causes of death are: cardiovascular and pulmonary complications, peritonitis, paralytic ileus, prolapse of small intestine, and mechanical obstruction. Stenosis of the colostomy opening is the most frequent late complication. Fixation of the colon with obliteration of the lateral space and immediate opening of the colostomy are stressed in the operative method.

Dennick reviews colostomy from its birth in 1793 by Duret and covers its evolution through the posterior approach and up to the present types. Two methods are now recognized, the spur type and division of the bowel with invagination of the distal end.

R. Best prefers the paramedian incision because muscle to muscle and fascia to fascia approximation give better support to the wound and where colostomy is indicated provides a better functioning colonic aperture. A number of interesting operative details in colostomies are described.

Salvin reports a new operation for rectal prolapse consisting of fixation of the rectum to the previously ventrofixed uterus and to the abdominal wall. He claims avoidance of injury to ureters and iliac vessels and obliteration of pouch of Douglas.

ABDOMINAL PAIN DUE TO INTRACRANIAL DISEASE

GASTRO-ENTEROLOGISTS will be much interested in a recent article by Wechsler on "Abdominal pain as a symptom of disease of the brain."* Frequently physicians see men and women who complain bitterly of abdominal pain which does not correspond to the distribution of any particular nerve or spinal segment, and which is not associated with any demonstrable disease in any part of the digestive, the urinary or the genital tract. In many of these cases several operations have been performed, and appendix, gall bladder and parts of the pelvic organs have been sacrificed without avail.

Oftentimes the pain is said to be continuous day and night for year after year, and yet the patient commonly continues to look fairly well. This, together with the fact that years of suffering have not ended in death or disaster, must always cause the attending physician to suspect that the trouble is a "functional" one. But this doesn't help to relieve the pain! Another thing that sometimes makes the physician suspect that the pain is not due to disease in the abdomen is his discovery that even a large dose of morphine has no effect on it. If the pain were arising in a distended bile duct, ureter, or segment of bowel it would almost certainly be relieved or moderated by morphine. Similarly, such pains commonly fail to let up after the blocking of posterior roots or splanchnic nerves with procaine.

Sometimes the physician will decide that the pain must be psychic in origin, but this doesn't help much because, as Foerster has said, in the last analysis all pains are psychic; they are all perceived in the brain. Doubtless what the physician has in mind when he speaks of psychic pain is that the distress arises in the brain and is projected to the periphery. Perhaps it would help to look on some of these curious pains and burnings as hallucinations of sensation, comparable with those which cause a psychopathic person to feel sure that he has a snake or a frog in his stomach.

Whatever the cause, it is certain that in most cases the patient suffers, and often a life is wrecked. That the suffering is severe is indicated by the fact that so many of these patients welcome one major operation after another.

It is helpful now to have Wechsler's report of fourteen cases of abdominal pain in which the cause appears to have been a definite lesion in the brain. That such things are possible has been known for years, but there still is much need for the reporting of cases of this type.

According to Wechsler, the pain was often cramping; in the different cases it came in different parts of the abdomen, every quadrant being represented in the

*Wechsler, I. S.: Abdominal Pain as a Symptom of Disease of the Brain. *J. A. M. A.*, 105:647-650, 1935.

list of sites. In several cases it was accompanied by nausea and vomiting, and in several the thing that should have put the clinician on his guard was the fact that the abdominal disturbances came at any time without relation to the taking of food. In other cases a useless appendectomy might have been avoided if more attention had been paid to symptoms which pointed to the presence of intracranial disease.

This does not mean that all the puzzling and at present unexplainable abdominal pains are from the brain; all it suggests is that this possibility should be kept in mind everytime a healthy looking patient appears with pain which is not affected by exertion or by eating or by the cycle of activity in any one of the organs in the abdomen.

Walter C. Alvarez, Rochester, Minn.

Uber die Rhythmik der Leber-funktion, des Stoffwechsels und des Schlafes. By Erik Forsgren. Publisher, N. J. Gumperts Bokhandel, Stockholm, 1935. No. of pages 56. Origin, Sanatorium Svenshögen.

PART I of this review is a consideration of the rhythmic changes in the liver of the experimental animal, hitherto described in scientific journals. The author describes this periodicity and alternation of the assimilatory and secretory activities of the organ. The secretory phase of the cycle is accompanied by an increased diuresis, increased heat production and rise in body temperature.

There are no data that the kidney itself has any intrinsic rhythm of its own; such rhythm as it does manifest is probably dependent upon the rhythm of the liver.

When rabbits have full access to food, the author learned that the peak of the assimilatory phase occurred about midnight, or some time thereafter. Secretory activity became evident in the latter part of the night or early morning and became more marked in the forenoon. The assimilatory phase then began in the early afternoon and reached its peak again near midnight. Much variation was encountered among the animals studied and no clear line of demarcation was consistent for all.

Although there is plenty of food in the stomach, the liver cell gives up its glycogen as the organ enters the secretory phase of the cycle. Since at least twenty-four hours is required for the emptying of the stomach of the rabbit, the author believes that the twenty-four hour variation in the liver is really due to certain astronomic factors to which the organism is subjected and not to the food factor. The twenty-four hour day is an astronomic concept; most men and animals sleep at night, rising with the sun and pursuing their round of activity in keeping with this twenty-four hour concept. The author is of the opinion that since our sense of sight is controlled by the cerebrospinal nervous system, the liver is no doubt controlled by the action of the vegetative nervous system in some similar way. Then, too, he believes that the rhythm of the liver may well be stimulated or changed by the action of certain hormones. In other words the author believes that the rhythmicity of the liver is due to certain intrinsic factors which are set in motion by some extrinsic astronomic mechanism, and that food is not a factor in elaborating this cyclic phenomenon.

The Second Part of this report concerns the author's study of certain clinical cases. Although the liver plays the dominant *rôle* in controlling rhythmic phenomena in the body, the kidney reflects this hepatic rhythm although having none of its own. During the secretory or dissimilatory phase of the hepatic cycle there is increased diuresis, a flood of water with dissimilation products, and an increase in body temperature.

The first clinical case reported was that of a normal man, thirty years old, who remained in bed during the period of observation. Adequate meals were provided at 9 a.m., 1:30 p.m. and 9 p.m. Body temperature, total urine, and nitrogen, urea and urobilin were computed at two-hour intervals. In a second experiment comparable data were obtained but the patient was fed at 7 p.m., 12 m. and 5 a.m. during the night rather than during the day. Variation curves were plotted covering the changes in the items indicated above. In general the author believes that a twenty-four hour rhythm maintains irrespective of the time food was taken. Knowledge of hepatic rhythmicity explains the changes which occurred in the kidney. During the secretory phase of the liver cycle, water is given off, explaining early morning diuresis. During the assimilatory phase the liver takes up water, and this explains the decrease in diuresis after the evening meal. The twenty-four hour variation in the urea output coincides with the variation in protein metabolism in the liver.

Forsgren's observations anent cyclic activity in the glycogen-forming and bile-secretory functions of the liver have been confirmed in the main by other investigators, notably by Higgins and his associates. The latter are of the opinion that the author places too much emphasis upon extrinsic or astronomic factors in the elaboration of this cycle and not enough upon food. They feel that when the consumption of food is rigidly controlled, these cyclic changes, particularly those concerning total weight, glycogen, and content of water, are largely dependent upon physiologic factors associated with feedings.

George B. Eusterman, Rochester, Minn.

SECTION X—*After "Hours"*

Causae Mortis*

By

VIRGIL E. SIMPSON, M.D.
LOUISVILLE, KENTUCKY

DEATH IN LITERATURE

"AND all the days that Adam lived were nine hundred and thirty years, and he died."

Death is universal. No sex is spared, no age exempt. The majestic and courtly roads over which monarchs pass, the way that men of letters tread, the path the warrior traverses, the short and simple annals of the poor—all lead alike to the grave.

Poets, essayists and orators have made death the theme about which they have rhapsodied, philosophized and grown eloquent respectively. As a theme it has bulked large since the earliest times of recorded literature. Epictetus philosophized about it and wrote: "Since death be daily before your eyes, then you will never entertain any abject thought nor too eagerly covet anything." Longfellow with poetic license in beautiful phrase pictured it as but a gateway through which mortals pass:

> "There is no death; what seems so is transition.
> This life of mortal breath is but a suburb
> Of the life Elysian which we call death."

Socrates, as might have been expected, declined to be perturbed about it, as is evidenced by his injunction, "Be of good cheer about death; know this of a truth, no evil can happen to a good man either in life or after death." Shakespeare, like a sentient plummet sounding every human emotion and almost every phase of human interest, is not looked to in vain for some expression concerning death. Thus we find him saying:

> "Sense of death is most an apprehension,
> And the poor beetle that we tread upon
> Feels a pang when it dies as great as
> When a giant dies."

Bacon expressed a great thought, withal perhaps a true one, when he said, "It is as natural for man to die as to be born, and to a little infant perhaps the one is as painful as the other." Michael Angelo, as might have been expected, linked death to love, and said, "Death and love are the two things that bear the good man to heaven." Sir Walter Raleigh, perhaps between smokes, said:

> "Of death and judgment, heaven and hell,
> Who oft doth think must needs die well."

Pope looked upon it as a great release when he said, "Death is the liberator of him whom freedom cannot release; the physician of him whom medicine cannot cure; the comforter of him whom time cannot console." Wordsworth is sometimes quoted as having said the good die young; what he did say was, "The good die first; they whose hearts are dry as summer's dust burn to the socket." Menander had long before expressed the essence of such a thought when he exclaimed, "He whom the gods love die young." Wonder is sometimes expressed concerning the reluctance of the anchorite to die. Jay commented on this theme thusly, "A dislike of death is no proof of the want of religion. The instincts of Nature shrink from it, for no creature can like its own dissolution."

With something of the same thought in mind, Montaigne wrote, "It is not death, it is dying, that alarms me." I like what Sterne said about it, "Death opens the gate of Fame and shuts the gate of Envy after it." But of all, I think perhaps I like best the words of Daniel Webster, "One may live as a conqueror, a king or a majesty, but he must die a man." And as the great leveler of us all, one is reminded of the story of Alexander the Great, who, seeing Diogenes looking attentively at the parcel of human bones, asked the philosopher what he was looking for. "That which I cannot find," was his reply, "the difference between your father's bones and those of his slaves." From Cicero came a paean of resignation: "To me Death is even now desirable, after all the honors I have gained and the deeds which I have done." "I must die," says Epictetus, "but must I die sorrowing?" In Hebrews IX:27 one reads: "It is appointed unto men once to die, but after this the judgment."

The late Dr. Osler set aside one corner of his library to what he impishly called "Death, Heaven and Hell" corner. The books in this particular section, old and new, dealt with spiritualism, dreams, ghosts, witchcraft, longevity, premature burials, cremation, etc. Here, too, could have been found Maeterlinck "On Death," of which Osler said in a letter published later in the Spectator in 1912 that he had read with some eagerness Maeterlinck's essay, but that he was much disappointed. Quoting him, he said, "There is an unpleasant flavor, a cadaverous mustiness about the essay which even the words cannot cover, and in spite of a plea for burning burials, one smells everywhere the mold above the rose." And then further along in that same letter which was published in the Spectator, he protested against the pictures then extent which had

*Read before the Society of Physicians and Surgeons, Louisville, Ky., October 17, 1935.
Submitted January 7, 1936.

been made of the act of dying. A few of those which he listed were, "The Pangs of Death," "The Awful Struggle," "The Sharpest Peak of Human Pain," "Tortures of the Last Illness." "The truth is," he said in commenting on these pictures, "that an immense majority of all who die, die as they are born—oblivious. A few, a very few, suffer severely in the body, fewer still in the mind." And then he quotes Shelley:

> "Mild is the slow necessity of death;
> The tranquil spirit fails in even breath.
> Without a groan, almost without a tear,
> Resigned in peace to leave this sphere,
> Calm as a voyager to some distant land,
> Full of wonder, full of hope, is he."

And further along he takes issue with what he calls a type of hysterical statement that all doctors consider it their first duty to protract as long as possible the most excruciating convulsions of the most hopeless agony. There are, he says, no circumstances contradicting the practice of Thomas Fuller's good physician, "When he can keep life no longer in, he makes a fair and easy passage for it to go out." "Nowadays," he says, "when the voice of Fate calls, the majority of men may, with Socrates, assert, 'I owe a cock to Asclepius.' A debt of thankfulness was his for a fair and easy passage."

Osler, it appears, always had a deep philosophical interest in the subject of death and soon after reading Munk's "Euthanasia" he wrote for the Canada Medical and Surgical Journal under date of March, 1888, the following, "We speak of Death as the King of Terrors, yet how rarely does the act of dying appear to be painful. How rarely do we witness agony in the last hour. Strict, indeed, is the fell sergeant in his arrest; few feel the iron grip; the hardest process of Nature's law is for most of us mercifully effective, and death, like birth, is but a sleep and a forgetting." He approves in that article of Munk's advocacy of the free but judicious administration of opium, not so much for the allaying of pain as for the relief from exhaustion,—of indescribable distress and anxiety—referred to the heart and stomach. Then he quotes Huseland, who declared 'Opium is not only capable of taking away the pangs of death, but it imparts even courage and energy for dying.'

It is said of Osler that though he suffered deeply in his last illness that he never permitted others to witness his suffering, that is, the evidence of his suffering. And Cushing says of him in connection with the loss of his only child that "he brushed his sorrow and his emotions aside with some remark which to the unknowing might have seemed almost flippant, "And if I laugh at any mortal thing 'tis that I may not weep."

"The doctors and the priests," said Napoleon, "have long been making death grievous." Well may one ask, how far correct was Napoleon? In every hospital one may witness the wreck of an accident or the victim of an infection hopelessly done for, but watch the doctor. He injects high-powered drugs into the tissues; gives glucose solution in a vein, starts a proctoclysis, fills the tissues with needles through which may gravitate normal saline. And then he rushes to the side of the stricken family and relates the story of his superhuman efforts, only to rush back to the bedside to futilely pump in the victim a serum. Why cannot the physician with a dignity in keeping with his place as a man of science, tell the family there is no hope, but that the dying shall go in comfort? Why cannot he in accord with old Seneca come to realize that the end of torture is the best part of that torture.

THE BIOLOGICAL ASPECTS OF DEATH

Shakespeare was pleased to divide the span of life into seven stages, but from a biological standpoint we can only make five divisions of the life cycle of individual multicellular organisms. Before considering these five phases of the life cycle, it is perhaps wise to consider the definition of some biologic terms. The word gamete means a sex cell, a cell that contains the parental inherited material, and since these are halved by a process known as reduction division, men say that a *gamete* contains one member of each pair of inherited factors. These inherited factors are called *genes*. When two *gametes* fuse, that is, the egg cell and the sperm cell, the result of this fusion is a fertilized egg cell, a cell that forms the starting point of a new organism, the name of which is the *zygote*.

The first phase of the life cycle, then, is the formation of the *zygote*. One may say that the life picture of the individual as a distinct biologic entity begins with this event. The second phase is the period of development and growth. This, naturally, can be divided into two sub-phases, (a) the embryonic or foetal phase and (b) the post-embryonic or post-natal phase. The duration of this growth phase of the life cycle of various kinds of multicellular organisms covers a wide difference, as for example, in the ordinary fruit fly this cycle is only about 8 days, whereas in man it covers about twenty years.

This, then, is succeeded by the third phase, the phase of adult stability, during which period there are no marked changes observable, either in the direction of growth or degeneration. Sometimes it is spoken of as "the prime of life." The duration, of course, is variable, but sooner or later the individual can be observed, even casually, to be beginning to pass into the fourth phase, which biologically is spoken of as the period of senescence. Here one sees evidences of the progressive waning in the intensity of the vital processes, along with the degenerative changes in the actual structure of the body. The duration of this cycle varies just as greatly as that known as the prime of life, but as Jeff de Angelis sang in that silly ditty, "A little bug'll get you some day," and sooner or later there comes an end to this phase, which introduces a final cycle in the life period of man, known as death. Of course, the individual life cycle may be terminated anywhere after the first phase has occurred, namely, the fertilization. Attractive as may be a consideration of the first three phases, we are particularly interested here only in the two last, the senescence and death.

The average period of the life cycle of the human family has been materially lengthened in the last two decades, or shall we say the last three decades. Thirty years ago, the average expectancy of human life was about thirty-four years of age; today it is well along beyond fifty-six. Attempts at explaining the variations of the life cycle of different species of multicellular organism have never been successful. As an illustration, at one time it was contended that the duration of an animal's life was somewhat in correlation with its size; as is well known, a parrot is much smaller than a horse and yet outlives it by many years. What is perhaps of greater interest and a more difficult solution is the individual variations of the life cycle in the

same species. Probably the most important influence in the difference between individuals, which finds expression in the varying degrees of longevity, are definitely inherited factors.

The statement that natural death is a novelty sounds rather unreasonable at first thought. Such a statement implies that neither senescence nor natural death is a necessary, inevitable consequence of life, yet biologists claim that the evidence in favor of such a statement is abundant. Some of the reasons which they urge for this statement is that various single cell organisms, such as protozoa, seem to be in a certain sense immortal, that is, they reproduce themselves by simple division of the body, one individual becoming two, leaving behind them in this process of division nothing which one would recognize as a corpse. And it seems from experimental work that this process can go on indefinitely without any evidence of changes corresponding to senescence and without any rejuvenating process, depending solely upon keeping the environment of the cells favorable. Then, an alluring thought is urged when one considers a germ cell of multicellular organisms in the sense that they are immortal. By this is meant that the germ cell is transmitted from one generation to the next, going on without death, whereas the body cells themselves die. The continuous cycle of propagation of the human family has gone on since the human family first made its appearance among multicellular organisms on the face of the earth.

Then this thought that natural death is a novelty is further borne out in considering certain low organized groups of multicellular animals in which the power of multiplication by budding off a portion of the body, which reproduces a whole, is retained. As long as this asexual mode of reproduction occurs, there is no place for death; in the passage from one generation to the next no residue is left behind. Such a conception of perpetuity in multicellular organisms finds its counterpart in the vegetable kingdom, for example, where the root stock of a perennial plant continues to grow indefinitely. The experiments of Carrel and Delind keeping alive the heart of a chicken embryo for now more than sixteen years, which is longer than the normal life span of a fowl, offers food for reflection. If this can be done in single instances, there seems every reason to believe that by the continuation of such technique the culture can be kept alive indefinitely. Such experiments have been carried out in other highly differentiated cells.

Thus nerve cells, muscle cells, connective tissue cells, epithelial cells, kidney cells, have all been successfully cultivated *in vitro*. It would seem that the foundation has been laid for the statement to be made that there is potential immortality for all essential cellular elements of the body. The question then arises, what causes death among multicellular animals, exclusive of violence. In considering an answer to this query, it might be reasoned that multicellular animals do not share in immortality because of the differentiation and specialization of function of cells and tissues and that in the bulk grouping of these cell tissues of the body as a whole some individual part does not find the conditions necessary for its continued existence. It would seem that it is this very differentiation and specialization of function of a mutually dependent body made up of cell tissue which ultimately results in death rather than to an inherent or inevitable mortal process in an individual cell itself. To quote the thought of one scientist, one reads:

> "When the cells show characteristic senescent changes, it is perhaps because they are reflecting in their morphology and physiology a consequence of their mutually dependent association and not any necessary progressive process inherent in themselves."

In other words, in the light of present knowledge it seems necessary to regard senescence, in part at least, as a phenomena of the multicellular body as a whole, resulting from the fact that it is a differentiated and integrated morphologic and dynamic organization. This phenomenon is reflected morphologically in the component cells, but it apparently does not primarily originate in any particular cell because of the fact that the cell is old in time or because that cell in and of itself has been alive, nor does it occur in the cells when they are removed from the mutually dependent relationship of the organized body as a whole and given appropriate physico-chemical conditions. In short, senescence appears in the present state of knowledge not to be a primary or necessary attribute of the physiological economy of individual cells as such, but rather of the body as a whole.

THE BREAKDOWN CYCLE OF DIFFERENT ORGANS OR SYSTEMS IN THE HUMAN BODY

In pursuing this thought to its logical conclusion, one must become impressed with the difference in time which seems to be characteristic with reference to the breaking point of different organs and systems of the human body. A part of this difference, of course, can be explained on the basis of exposure, a part of it to environmental stress and strain, but there still remains a wide zone which seems to have nothing to explain the time element of breakdown other than that it is just an inherent condition of the structures themselves. An interesting study would come out of this if one looks at the mortality returns in the registration areas of the United States.

TABLE I

Deaths due to organic breakdown or failure of organic systems	Mean age at death (years) Male	Female
1. Alimentary Tract and associated organs of digestion	25	28
2. Respiratory System	32	32
3. Skeletal and Muscular Systems	35	37
4. Endocrinous System	44	44
5. Skin	46	42
6. Reproductive System	47	42
7. Nervous System	49	51
8. Circulatory System, including blood	54	54
9. Excretory System, (kidney and associated structures)	57	54

Considering the figures in this table one is impressed with the differences in time of senescence and ultimate death of different organs or systems in the body. Death in the alimentary tract and associated organs of digestion occurring at an average of 25-28 years as compared with a kidney death at a bit more than 57 years can be explained on no other basis. Of course, environment, that is, external environment, is playing a tremendous *rôle*. In the deaths from the digestive system and respiratory system it must be remembered

that these two systems are constantly in contact with external agencies, such as food and air, while at the bottom of our list the circulatory and the excretory systems do not come in such direct contact.

One may conclude this phase of our consideration of death with the statement that many theories of senescence have been advanced. No one can be regarded as entirely satisfactory. Most of them have the logical defect of setting up some particularly observed atrophy or element of the phenomena of senescence itself, such as the slowing rate of metabolism or protoplasmic hysteresis, offering these as an explanation as to the cause of the whole. Since the question is not yet settled, experimental work must continue, particularly in the direction of producing at will or keeping under control at will the phenomenon of senility without retardation.

THE ETHNOLOGY OF DEATH

The savage of all times and all lands fails to understand death as a natural phenomenon. To him it is inexplicable as a result from natural causes. When he dies without being wounded he is thought to have been the victim of evil spirits with which he has consorted. In Africa the death of a person is usually ascribed to a magician, particularly the magicians of some hostile tribe, or to the malicious act of a neighbor, and this thought has been transplanted with the bringing of the institution of slavery into our country. It is surprising, even at this late date, the tremendous influence which the superstitions of the African negro have had upon the thought of the American people, particularly, of course, those of the South. The peasantry of many countries believe now that disease is the work of demons and in several of them, for example in Australia, death, no matter how evident it may have been the result of natural causes, is usually set down as due to witchcraftry. Among such peoples sleep and trances are regarded as temporary absence of the soul; death is regarded as the permanent absence of the soul, the soul being regarded, so far as they think of it, as the vital principle of the body. This vital principle may be diffused throughout the body according to the thought of some peoples, whereas in others it is believed to be concentrated in one organ. This has given rise to such sports as head-hunting. The term may be personified, as for example, it is sometimes spoken of as the destroyer of life. Conventionally, Death is usually represented as a skeleton with a scythe. An example of the personification of the term occurs in one of Young's lines, which reads:

"Death! Great proprietor of all."

Then the term is also used figuratively, meaning to the last extremity, or utterly, or beyond endurance, as "sick of death" or "tired to death" or to "laugh oneself to death."

DEFINITION OF DEATH

The definition commonly given to death is that it means a cessation of all vital functions without capability of resuscitation. Or again, it may be defined as the permanent cessation of the vital functions of the body. The word as we use it today is the English representative of a similar word common to the Teutonic languages. It means that the ultimate origin of the word comes from the pre-Teutonic verbal stem, "dau." The Swedish and Danish language has the word dead; the Dutch dood; the German dod. There are several synonyms more or less commonly used; deceased is the legal term in ordinary use, thought to be slightly euphonistic or, at least, rhetorical. "Demise" originally was the term used in referring to the death of royalty or some other illustrious personage. It later came into common usage and might be described as a somewhat grandiloquent term for death. Church persons and particularly members of certain religious organizations seem to prefer the words "passed on."

KINDS OF DEATH

(A) Molecular death means the death of a part of the body of a local nature, such as dental caries or necrosis or gangrene.

(B) Somatic death, which means the death of the entire body.

Then one must also make a division of the occurrence of death with reference to the time element if a sane study of the causes is to be made. (a) Chronic causes, or slow causes of death, which connote any continued disease such as tuberculosis or Bright's disease or heart disease of a chronic organic character. These chronic diseases produce relatively slow degenerative changes which after a time, sometimes because of their sum total of alterations from normal, result in the cessation of life. (b) Sudden causes of death. It is under this heading, I think, that the majority of errors are made in listing causes of death; errors because of inability to secure consent of the family for autopsy study, or because of a willingness to save the family from the distress of having an official inquiry into the cause of death, or a willingness to assume responsibility and merely guess at the cause; and, finally, because of a sincere belief that the cause of death is known, though really ignorant as to the actual condition.

THE INTERNATIONAL LIST OF CAUSES OF DEATH

The Bureau of the Census of the Department of Commerce and Labor of the United States Government has issued a list of causes of death known as the International List. It is urged on physicians that the nomenclature adopted by this list be followed in making out their vital statistics returns. There is some argument in favor of the widespread use of such a list in that it does tend a bit more toward scientific accuracy and also does, by virtue of conformity, increase the value of vital statistical returns.

This list sets down more than 250 conditions and diseases as acceptable terms with which to explain death. It might be asked if the list is not unduly lengthy. Yet its inadequacy is admitted when at the end of a section one reads, "Other Diseases." Likewise, one finds the injunction, "never report mere names of symptoms"; it objects to the term "uremia," but accepts "diarrhea"; it agrees to "lack of care" but turns thumbs down on "asthenia"; it says "no" to "ascites" but thinks "chyluria" is splendidly descriptive. "Congestive heart failure" is thought just too utterly provincial, but it nods approval to "pulmonary emphysema"; "surgical shock" just won't do but death by "lightning" is entirely enlightening; "pulmonary hemorrhage" is frowned on, but "uterine hemorrhage, nonpuerperal" is awarded a smile; "homicide by fire-

arms" is no more descriptive than "laparotomy by the surgeon"; why "Pott's disease" is any more descriptive than "white swelling" can only be guessed.

The List is much in need of revision, even remaking. With no thought of offering a classification of the causes of death to replace the International List, but rather for the purpose of simplifying the subject in order that some discussion of the modes of death may be had, the following would seem to meet the requirements:

CAUSES OF DEATH

1. Hemorrhage	8. Hormone Loss
2. Asphyxiation	9. Degenerative Changes in Vital Organs
3. Shock	10. Vascular Changes in Vital Organs
4. Starvation	11. Mechanical
5. Cerebral Anoxemia	12. Congenital Malformations and Anomalies
6. Exhaustion	
7. Paralysis	

This list may not appear adequate, but it surely covers the problem as thoroughly as any I have seen and, at least, has the merit of being original. It would appear useful to inquire into the mechanism of these general causes of death.

(1) *Hemorrhage.* This heading would also include the rupture of aneurysms. Obviously, the size of the vessel involved will determine death or survival of the individual. The larger the vessel the more inevitable the result.

The total volume of blood is from 5 to 7 per cent of the weight of the body. 40 to 50 per cent of this volume is composed of corpuscles. One of the intermediate effects of hemorrhage is fall in blood pressure. The loss of 5 c.c. of blood per kilogram of body weight does not influence pressure; the loss of the next and each succeeding 5 c.c. reduces the pressure about 6 mm. Hg. When a pressure of 50 is recorded the danger limit has been reached; a pressure of 30 makes recovery uncertain, and now symptoms of shock supervene. A loss of 3 per cent or less of body weight from hemorrhage should permit of recovery.

A second effect of hemorrhage is an increase in the pH of the blood plasma. This is followed by a third effect, viz., a reduction of the store of alkaline reserve. Hemolysis occurs, the consequence of dilution of the blood, the plasma becoming definitely reddened. And finally, the loss of the red corpuscles with their cargo results in anoxemia.

(2) *Asphyxiation* may bring about death by interference with the replacement of alveolar air or by the continued inhalation of air poor in required constituents. The first may result from failure of the chest wall to keep in action, as in convulsions, or from a mechanical obstruction, as a foreign body in the larynx. Water may act as such a foreign body, but it should be remembered that one may die after falling in water by shock, concussion, heart failure, hemorrhage or violence. The spasmodic contractions of skeletal muscles commonly preceding death from asphyxia result from the increased excitability of the reflex centers of the cord. The heart slows partly because of hydrogen-ion concentration in the blood and partly because of increased intracranial pressure. Oxygen deprivation excites the vaso-motor constrictor centers, blood pressure promptly rises and hyperpnea results. When the CO_2 percentage of respired air rises to 6 and the O percentage falls to 13.5 it becomes unbearable. A lowering of the alkaline reserve of the blood, reduction of CO_2 tension and hyperpnea all result from a deficiency of oxygen supply. The resulting stimulation of the respiratory center causes a blowing off of CO_2 from the blood into the alveolar air. The pH of the blood is lessened and alkalosis is established. Increased respiratory effort will not relieve the asphyxia because the hemoglobin holds the O with great avidity. If damage to pulmonary epithelium occurs slowly O hunger may not cause respiratory center activity and then the clinical picture of a livid cyanosis wdithout hyperpnoea is seen.

(3) *Shock may kill.* It is the result of many causes. It presents the phenomena of a varying degree of paralysis of the sensory and motor portions of the reflex arc, profound disturbance of the circulatory and respiratory systems and a subnormal temperature. In attempting to classify shock it would appear reasonable to include (a) *gravity* shock, which is the result of stagnation of the blood in the splanchnic vessels. The nerve centers in the brain and cord are rendered anemic. In man the upright posture does not cause gravity shock because of the valves in veins and the *vis a tergo.* (b) *Hemorrhage* shock results in an inadequate filling of the heart with blood during diastole. The effects of hemorrhage have been described. (c) *Anesthesia* shock may be either a primary or secondary condition. The condition seen in the earlier stages of a badly given anesthetic resulting in paralysis of the heart or respiratory center is not shock. A case that has recovered from primary shock, the result of an accident, may have a secondary shock brought about by an anesthetic. (4) *Spinal* shock may result from section of the cord and presents no difficulty in identification by virtue of its local character. (5) *Toxic* shock is best illustrated by the phenomenon known as anaphylaxis. It may result from septic processes through absorption. The shock resulting from intestinal obstruction is now known to be due to absorption of a proteose from the obstructed loops. (6) *Nervous* shock is best demonstrated by the "shell" shocked soldiers in the Great War. Many of these developed the condition after leaving the front. (7) *Surgical* shock is the variety most commonly present when shock is referred to without qualification. It results from accidents, extensive manipulation and especially when there has been extensive muscular destruction. The clinical picture resembles cholera very closely and is a rather common clinical picture.

While the classification just given is a working one, it must be borne in mind that the clinical condition of shock is usually the result of a combination of several factors—hemorrhage, toxins, anesthesia and mental reactions.

(4) *Starvation* may cause death either because of a general failure of all the cells in their functions or because of injury of certain organs that are essential for maintenance of life. That the latter is the more likely factor is evidenced somewhat by the fact that during starvation the loss of protein from the body as a whole rarely amounts to more than 50 per cent at the time of death and it would seem unlikely that general failure of cell function could be the cause. If

it were, death would always occur when a certain fixed loss of protein had occurred.

Certain organs evidently cease to function either because they are deprived of raw material for the elaboration of some substance, such as a *hormone*, which is necessary for life, or because they wear themselves out from sheer lack of nourishment. Starvation usually ends in death in the adult in something over thirty days; it is very much sooner in children because of their more active metabolism. The total loss of body weight at the time of death from starvation may be as much as 50 per cent of the original. The body temperature does not change greatly until within a few days of death, when it begins to fall. The blood sugar drops rather rapidly early in the starvation period, but after it reaches a varying level it remains fairly steady thereafter. This is explained by the fact that practically all available glycogen has been used up after the first three or four days of starvation. The available glycogen thereafter is derived from the proteins and fat of the body of the person being starved. Even the glycogen content of the skeletal muscles is reduced. The condition of acidosis supervenes. The acids responsible for the condition are derived from the incomplete combustion of fat. This may amount to as much as 10 or 15 grams per day, particularly in obese individuals. During the greater part of the starvation period most of the energy required to maintain life is of fat derivation. When the available supply has become exhausted, then protein metabolism sets in at an increased rate and as a consequence the nitrogen secretion rises. When this occurs it may be considered as a harbinger of death and is sometimes spoken of as the "ante-mortem rise in nitrogen excretions." It really means that all of the fuel of the animal economy has been used up, or in other words, that the working capital has been exhausted.

(5) *Cerebral anoxemia.* The physiological integrity of the cerebrum is an essential factor in the preservation of consciousness. The exact nature of this state of awareness is not known, but a number of factors on which it depends are known. One of these is the maintenance of the blood supply. Whatever raises the cranial cavity pressure above that of the cerebral veins and capillaries causes obstruction to cerebral circulation in varying degrees to the absolute. Tumor, abscess or hemorrhage, by pressure, produces symptoms first of cerebral structures, but is prevented from pressing on medullary vessels by the falx cerebri and cerebelli. But as the brain stem is pressed downward the medulla is pressed against the foramen magnum and failure of respiration or circulation or both ends the drama. Also general circulatory conditions affecting the amount of carotid blood supply will affect consciousness. Prior to anaesthesia days, pressure on the carotids was resorted to for the induction of unconsciousness. When the vasomotor tone of the abdomen is lost, most of the body blood can gravitate there, and unconsciousness results. Even the pooling of blood in the skin vessels, as when taking a hot bath, may cause syncope. Removal of fluid in pleurisy or in ascites may, if done rapidly or too completely, cause syncope. Carried beyond certain limitations, any of these conditions may cause death.

By anoxemia one intends to mean a tissue oxygen want instead of respiratory inadequacy. It is distinct from carbon dioxide retention, though it may be coincident with it. An anoxemia may obtain with a normal CO_2 in the blood. Of it Haldane wrote, "It not only stops the machine, it wrecks the machinery." By forced breathing one may induce a respiratory center anoxemia in which condition there is no carbon dioxide retention. Another illustration is found in carbon monoxide poisoning, in which condition the hemoglobin is saturated with the gas to the exclusion of oxygen, hence anoxemia. It is anoxemia that limits man in search of new altitudes. Carbon dioxide is below normal in lobar pneumonia because of anoxemia, which causes hyperpnea, and this in turn washes the carbon dioxide out of the blood.

A reduction of carbon dioxide in the blood not only withdraws the physiological stimulus to the respiratory center, but hinders the dissociation of oxygen from hemoglobin. While all tissues present evidences of oxygen hunger, those of the nervous system have been demonstrated to be peculiarly sensitive. Barcroft classified anoxemia into (a) anoxic, (b) anemic and (c) stagnant. Such a grouping merely means that there may be an inadequate oxygen absorption from the lung, a blood under-laden with oxygen or a poor delivery of a blood normally loaded. They all imply oxygen debt and when the physiological adaptation of the circulatory apparatus cannot fit itself to the situation, distress even to the extent of death may supervene.

The syndrome of anoxemia must of necessity be either local or general. A disturbed digestion, for example, may result from a poor gastric circulation; an embolus blocks a vessel and an area of tissue is deprived of blood supply, with pain, edema and necrosis resulting. When the central nervous system is involved, restlessness, irritability, delirium, coma, death follow in slow or rapid succession as determined by the degree of oxygen want.

(6) *Exhaustion* may constitute a mechanism of death, the result of numerous agencies. But the conception should be limited to those agencies which, directly or indirectly, induce a state of exhaustion of cellular structure. Exhaustion derives from *exhaurire*, a term conveying the thought of "using up, to empty." While sharing some features in common with starvation and paralysis, it would seem to rank a special place in the causes of death. Some agents may cause this by the circuitous route of over stimulation; strychnine, primarily, activates the cells of the spinal centers, the medullary centers being indifferently involved. The drug is even more selective in its action, the primary stimulating or convulsant effect being confined to the sensory, not the motor cells of the cord. It is true that asphyxiation may become a part of the picture in death from strychnine, but it in turn is a result of exhaustion of the respiratory centers from over activity. While death may occur in strychnine poisoning because of respiratory spasm during the convulsant period, the usual cause is exhaustion of the spinal cord, medulla and sometimes the cardiac muscle.

A number of other poisons belong to this *convulsant* group. The picrotoxin group and the caffein group are ready examples.

(7) *Paralysis* might be defined in this discussion, in which the term is given a place in the causes of death, as a loss of function by direct depression. Some poisons produce death with no intervening stimulating period; a stage of irritability may supervene, but not

true stimulation. In this group will be found the toxins of such organisms as tetanus bacillus, the bacillus of diphtheria. such poisons as snake venom, alcohol, some anesthetics, many of the agents in the hypnotic and narcotic groups and such disease entities as progressive bulbar paralysis and acute ascending paralysis. When the effects of such agents are confined to non vital organs only local paralysis ensues. Death results when vital organs are attacked.

(8) Some of the *endocrine group* are essential to vital processes. A kind of vegetative existence can be maintained without thyroid function; life is not dependent upon gland activity. But some of the group are essential, e.g., the pituitary, the parathyroid and the adrenals. The problem of hormone loss is made complicated by the interrelationship in function. But such dependency strengthens rather than weakens the thesis of death from essential hormone loss. Whatever causes may establish this hormone loss are, of course, thus indirectly responsible for the death.

The next heading, Degenerative Changes of Vital Organs, might thus be conceived to remove the necessity for the listing of hormone loss as a cause, but not all of the diseases of these glands are degenerative. It may be acknowledged at once that many of the causes here considered necessarily overlap.

(9) *Degenerative Changes in Vital Organs:* Degenerative changes, when complete, cause death of any organ or cell. As stated under another heading, when local there is local death, and when vital organs are subjected to such processes death of the whole body occurs. If one embraces in a definition of the term degeneration a conception of a retrogressive pathological change in cells or tissues, in consequence of which the functioning power is lost and the living substance becomes converted into an inert mass, then may one appreciate the importance of this heading as a cause of death.

Then, too, if one pursues the subject a bit further and takes cognigence of the many kinds of degenerative changes a cell or tissue may undergo, it must be apparent that degenerative changes of vital organs bulk large as causes of death. Of these kinds, fatty, amyloid, angiolithic, hyaline, cystic, Wallerian, come readily to mind.

It is of importance to remember that degenerative changes in a peripheral nerve may be repaired by regeneration, whereas destruction of fibers in the central nervous system results in a permanent damage or death.

(10) *Vascular Changes in Vital Organs.* It requires no effort to establish complete obstruction of one of the main coronary arteries as a cause of death. Such a disaster may result from a thrombus, an embolus or obliteration of the lumen by multiplication of mural tissue.

That a spasm of vessel walls may cause death by local anemia is more equivocal. Yet experiments have demonstrated that complete anemia cannot be survived after a rather fixed period of time—a period which varies with different cell structures. Cerebral cells cannot be restored after eight minutes of anemia, medullary cells thirty minutes, while myenteric cells may live after seven hours. Such susceptibility helps explain why consciousness is lost early after circulatory failure of the brain. It also helps one to understand why such a faithful relationship obtains between the nutritional demands of a structure and its vascular distribution. The grey matter of the medulla has a richer capillary network than has that of the cord. Sensory neurons are in an almost constant state of activity, while the motor neurons exhibit a more intermittent activity; hence one is not surprised to find the former more richly vascularized than the latter.

(11) *Mechanical Causes.* But little space need be devoted to this section. The relationship between cause and effect is sufficiently apparent where grosser injuries are involved. Here the trauma is sufficiently massive that when vital structures are wrecked there is small need for invoking shock, hemorrhage and other fundamental causes as contributing factors. A piece of metal driven through the medulla kills by virtue of physical destruction; a similar damage of the nodal tissue around the mouths of the great veins in the right auricle kills at once. Birth trauma accounts for 34 per cent of deaths in the newborn and it is of interest to note that of this group of birth traumas 81 per cent was due to a tear of the tentorium cerebelli.

(12) Finally, 5 per cent of deaths of the newborn are due to *congenital malformations and anomalies.* Many of these are self explanatory and inconsistent with life, especially involving the central nervous system and the heart. Anacephalus, meningocele, hydrocephalus internus, stenosis of the conus pulmonalis, transposition of large vessels, a three-chambered heart, eventration, are a few of the more common; and the list is not exhausted.

DEATH RATE

Death rate is a term that arbitrarily expresses the mortality of a place based on the number of deaths for each one thousand of its population during a period of one year. To determine the death rate of a given place, multiply the number of deaths by 1,000 and divide the product by the population. So many factors influence the death rate of any community that a single yearly study of states or cities affords little real insight into the actual statistical death rate. To be worthwhile such a comparison must be made over a period of several years, say ten, hence it is obvious that the comparison of death rates of different communities for a short period may be markedly modified by the presence or absence of an epidemic of some acute transmissible disease, which might run a death rate for a given short period up 20 or 30 or 40 per cent higher than the average death rate when considered over a long period of time. For example, one might take the death rate of Seattle, Washington, for the year 1913, when it was 8.4, and compare that rate with the rate of Richmond, Virginia, which in the same year was 20.4. Certainly no such disparaging health ratios exist between the latter and the former city if studied over longer periods.

Likewise, the incidence of mortality is not equally distributed over all age periods. The rate is highest at the two extremes of the life span. A population with a high birth rate or one with a high average life span would have a high death rate when all ages and both sexes were considered only as components of the group. This form of determination is called *crude death rate* and must be reckoned as an unsound basis

for comparison of relative mortality of one country with another.

For such comparisons what is known as a *standardized death rate* should be used. To obtain such rates it must be found what the death rate would have been if the population had been made up as to sex and age on a fixed basis. Even this method is subject to objections, for such rates must vary according to the standard adopted. Therefore, the only accurate method is to use rates based on figures obtained from studies for different sex and age groups. The factor of sex must be included, since in most countries the death rate of males is higher than in females. There being more widows than widowers explains the remarkable fact that more than fifty per cent of the wealth of this country is in the hands of women.

A comparison of the death rate for various countries is given in Table II. It is necessary to make clear that these comparisons are drawn on a *crude death rate* basis, as explained above.

TABLE II

Comparison of Death Rate in Different Countries

	Years			
Country	1876	1901	1913	1926
England	20.9	16.9	13.8	11.6
France	22.6	20.1	17.7	17.5
Germany	26.3	20.7	15.0	11.9
Italy	28.8	22.0	18.7	16.8
Netherlands	23.5	17.2	12.4	9.8
Sweden	19.6	16.1	13.6	11.8
Switzerland	24.3	18.0	14.3	11.7
Australia	17.6	12.2	10.8	9.4
New Zealand	11.8	9.8	9.5	8.7
Japan		20.4		21.2

These tables indicate a definite decline in all the countries except Japan. The least improvement is shown by Germany and Italy. In some the rate has fallen as much as 50 per cent. This decline has not been spread over the whole life span. Since 1876 it was 65 per cent under five years of age and only 32 for 70 to 80 years in England, while in the U. S. it has been 40 per cent in 44 years. In New Zealand the decline has been but 26 per cent, which must be interpreted in the light of the lowest rate at the beginning of the period studied of any nation in the group. It would appear that New Zealand's figures might be accepted as an expression of the existence of an irreducible minimum.

Figures for the U. S. covering these periods are not available to the writer at present, but the nearest comparable rates are given in Table III.

TABLE III

Death Rates for U. S. in Each Decennial Census Period

Census Period	Rate
1880	19.8
1900	17.6
1910	15.0
1920	16.2
1930	11.8

THE TERM IN MEDICAL JURISPRUDENCE

The law divides death into two kinds, natural death and civil death. Natural death is defined as "cessation of life." The law considers a natural death as one which occurs by the unassisted operation of natural causes as distinguished from what is known legally as a "violent death," which is defined as one caused or accelerated by the interference of some human agency. The law defines "civil death" as the state of a person who, though possessing natural life, has lost all his civil rights and, as to them, is considered dead. Thus, a person attained and convicted of felony and sent to State prison for life, in consequence of conviction and sentence, is considered as civilly dead. This doctrine was handed down from the common law of England. Then the law makes some distinction between the term "real death" and "apparent death" and says that real death is distinguished by the absence of heart beat and respiration.

The law also sets up certain signs or indications by which it can admit that death has occurred. For instance, (1) when the body is the temperature of the surrounding air; (2) intermittent shocks of electricity of different tensions give no indication of muscular irritability; (3) movements of the joints of the extremities and of the jaw showing more or less rigor mortis; (4) a bright needle plunged into the biceps and left there shows no sign of oxidation on withdrawal; (5) the opening of a vein shows the blood has coagulated; (6) the subcutaneous injection of ammonia causes a dirty brown stain; (7) a filet applied to the arm causes no swelling of the veins on the distal side; (8) after death there is an absence of the translucency when the hand is held before a strong light with the fingers extended but not in contact; (9) after death there is a loss of pupillary reaction to light and to mydriatics, as well as a loss of corneal translucency.

THE LEGAL CONSEQUENCES OF DEATH

The burden of proof rests with the party who asserts that a person is dead. In other words, the law presumes that a person who is once shown to have been in life is presumed thus continued until the contrary is shown. The law does not even accept the record of probation of a will as competent evidence of death of the man who wrote the will. Out of the French civil code grew the attempts to determine the question of survivorship when several persons perish together as the result of the same event, such as a shipwreck or a battle or an accident, etc. Strength, age and difference of sex of the parties dying together constitute the factors around which the attempt is made to make such differentiation. For example, if of those dying one was under fifteen and another was thirty, the eldest was presumed to be the survivor. If all were over sixty, but one only sixty-one, that one was presumed to be the survivor. If all were presumably the same age, the male was presumed to be the survivor. The civil code of Louisiana laid down such rules, but the rest of the states of this country, which have derived much of their law from English common law, have never adopted these provisions and require that survivorship of two or more shall be proved by facts, not by any settled legal rule or prescribed presumption.

As to contracts in general are not affected by death of either party. The executors or administrators of the deceased are required and expected to fulfill all of his engagements and may enforce all of those in his favor.

While this statement is made as a general rule, of course there are exceptions, as for example, the contract of marriage necessarily must be terminated by the death of one of the parties. Likewise, a contract for partnership.

Something of the same rule applies with reference to crimes. If a person who is accused of a crime dies before trial, no procedure can be had against his representatives or his estate or heirs.

As to inheritance when a person possessed of real estate or personal property dies after having made a will, his real and personal property after satisfaction of his debts is to be distributed as directed in his will. But if one dies intestate, his real estate goes to his heirs as a law under the Statute of Descent of that state, while his personal property goes to the administrators to be distributed to the next of kin under the Statute of Distribution of that state.

The term "dead-born" means that a child born dead is to be considered as if it had never been conceived or born. In other words, it is presumed that it never had life, as it is a maxim of the common law that *mortuus exitus non-exitus*. It is also a doctrine of the civil law that not to be born and to be born dead are equivalent terms; the Latin is *non nasci et natum mori*.

DEAD BODY

The law defines a dead body as a corpse and sets up the dictum that there is no right of property in the ordinary sense of the word in a dead human body. There are, however, certain rights attached to it which the law protects and for the health and protection of society it is a rule of the common law, and has been confirmed by statute in many states, that public duties are imposed on public officers and private duties upon husband or wife or next of kin of the deceased, to protect the body from violation and see that it is properly buried and protected after burial. The executors, for example, have a right to possession of the dead body to preserve it for burial. The right to make testamentary directions as to the disposal of the dead body has been conferred by statute in a number of states. It has generally been decided that in the absence of testamentary disposition, the right and duty of burial devolves upon the relatives in the following order as named,—(1) husband or wife, (2) children, (3) father and mother, (4) brothers and sisters, (5) next of kin. The law also holds that the expenses for a funeral are necessary expenses and for which the estate of the deceased is held liable. The leaving unburied of a corpse of a person for whom one is bound to provide Christian burial is an indictable misdemeanor if it can be shown that he had been of ability to provide such burial. Any householder in whose house a dead body lies is bound by the common law, if he has the means to do so, to inter the body. To disinter a dead body without lawful authority, even for the purposes of dissection, is a misdemeanor for which the offender may be indicted under common law. Some of the States of the Union have statutes that make this offense punishable. It is not considered under common law to be larceny to steal a dead body, but if one steal the clothes from that dead body, he then can be charged as guilty of larceny. The right of burial having once been exercised by the person charged with that duty gives him no right to the corpse except to protect it from unlawful interference. Autopsy may be made by a physician under legal direction and at the request of the crime has been committed and he does not render himself liable by removing, for instance, a portion of the skull under the direction of the coroner.

It is the coroner's duty after death by violence to cause an autopsy to be made. The physician who makes it can recover from the local government for his labor. The matter of ordering autopsies and the dissections of dead bodies or exhuming them for that service has been regulated by statute in nearly all the states of this country. The preventing a dead body from being interred is an indictable offense in most states. The purchaser of land upon which is located a burial ground may be enjoined from moving bodies therefrom if he attempts to do so against the wishes of relatives or next of kin of the deceased. Every burial is a concession of the privilege that cannot afterward be repealed and the purchaser's title to the ground is fettered with the right of burial. However, the right of a municipal or state authority, with the consent of the owner of the burial lot or in execution of eminent domain, to remove dead bodies from cemeteries is a well settled fact in law. Neither can one seize a dead body on the pretense of arresting it for debt, and such seizure is considered *contra bonus mores* and an extortion on the relatives. Some states provide by statute that such an act is a misdemeanor. A widow who permits her husband to be buried in a certain place may not disturb his remains, her right to the body of her deceased husband being terminated by the burial and any further disposition of such body belonging thereafter exclusively to his next of kin.

THE TERM IN THEOLOGY

Here it is intended to mean the cessation of spiritual life and therefore comes to be called spiritual death. Such a conception is an essential part of particularly the Christian and Jewish religious. By inference spiritual death may be conceived of as an alienation from God or as an annihilation of the spirit in consequence of sin, as for example, in Romans 8:6 one reads, "To be carnally minded is death."

SECTION XII—"*The Clinic*"

"Milk of Calcium Bile"-- A Report of Two Instances*

By

BENJAMIN M. BERNSTEIN, M.D.

and

DANIEL DIAMOND, M.D.

BROOKLYN, NEW YORK

THE finding of "milk of calcium" in the gall bladder as a cause for abdominal symptoms is sufficiently frequent to warrant the report of cases as discovered. We, therefore, offer a discussion of the following two cases for consideration and stimulation. Both were correctly diagnosed pre-operatively by cholecystography:

Case I. F. K., White, Female, Housewife, age 34 years. Since the birth of a child 10 years prior to date, she complained of recurrent attacks of sharp pain in the right hypochondrium, radiating to the right sub-scapular area. Each attack was accompanied by nausea and vomiting, lasting several hours and frequently relieved by heat. There was no relationship to food intake. Attacks have come on more frequently in the last few years. There had been no jaundice.

On examination, there was marked tenderness in the gall bladder region and a suggestive palpable mass. Cholecystography revealed several calcified shadows in this region, one somewhat irregular, identified as a stone in the cystic duct, the other changing its appearance at different times and at different angles. There was no filling of the gall bladder after the oral administration of the dye.

Operation: A subacutely inflamed thick walled gall bladder was found and removed. On palpation it appeared to contain a sandy substance with a definite stone in the cystic duct as seen on the X-ray film. There were no adhesions, no calculi in the common duct. The appendix, likewise, was removed.

Pathological description: "The external surface of the gall bladder found smooth and glistening, the mucosal surface is trabeculated. The lumen contained 15 c.c. of colorless mucinous fluid and approximately 5 c.c. of a chalky white material having the consistency of "cottage cheese." The lumen of the duct is occluded by a white coral-like concretion. No chemical examination of the contents was made."

Diagnosis: "Milk of calcium bile"; sub-acute cholecystitis; cystic duct block by calculus.

Case II. This case is reported through the courtesy of Dr. M. J. Matzner of our department.

T. F., Female, Housewife, age 52 years.

Fourteen days prior to admission, patient had an attack of generalized abdominal cramps, localizing in the right upper quadrant with radiation to the right lower back. This pain was accompanied by nausea, no vomiting. Six days later, and again the night before admission, patient experienced similar attacks. There had been no jaundice at any time.

Physical examination: Revealed moderate tenderness in the right upper quadrant with no palpable mass.

Laboratory findings: Urine: showed the presence of bile and ½% of sugar. Blood: 15,000 RBC and a poly count of 89. Blood count showed a slight anemia; icteric index was normal; bilirubin showed a direct immediate positive and an indirect of 8 units. Blood chemistry: showed a somewhat low urea and high uric acid.

X-ray examination: showed a calcified semi-lunar shadow in the gall bladder region, several small calcareous shadows likewise seen above that. At a later period, after the administration of the dye, there was no increase of this shadow except for a diffusion of shadow on several of the films.

Operative findings: The gall bladder was adherent to the omentum; was distended; its walls opaque and thickened; did not empty readily. Cholecystectomy was performed.

Pathologic description: "The gall bladder had a red, granular, serous surface with markedly thickened walls; the mucosa was hemorrhagic and covered with small amount of inspissated, clay-like material with an occasional small stone of soft consistency.

DISCUSSION

That calcific deposition within the gall bladder either of stones or as so-called gravel or as "milk of calcium," as found in these two cases, can be productive of symptoms, has been known for years. It seems superfluous to review the previous reports by other observers. The article by Kornblum and Hall in the American Journal of Roentgenology in May, 1935, covers these very thoroughly. However the importance of this contribution is in the discussion and study of the X-ray findings. A semi-lunar, calcified shadow in the gall bladder region which is present on the control or zero hour film and persistent at all times, should

* Division of Gastroenterology, Department of Medicine, Jewish Hospital, Brooklyn, N. Y.

Submitted April 4, 1936.

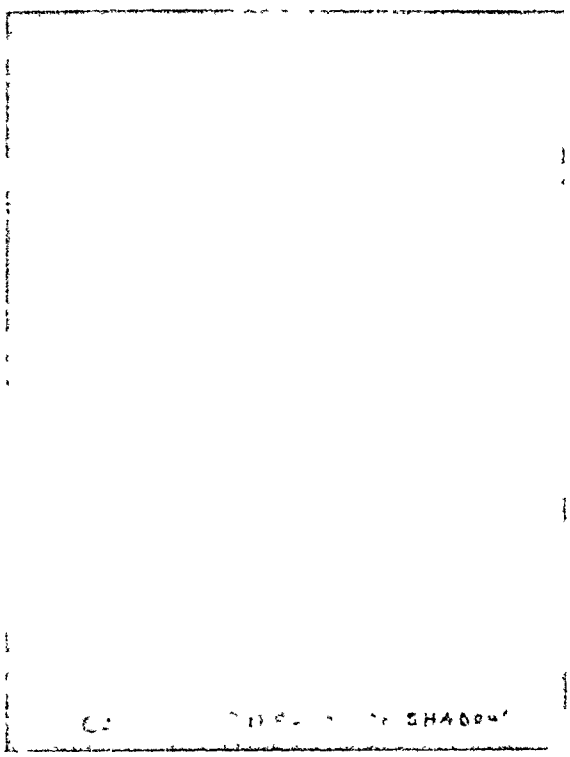

Fig. 1

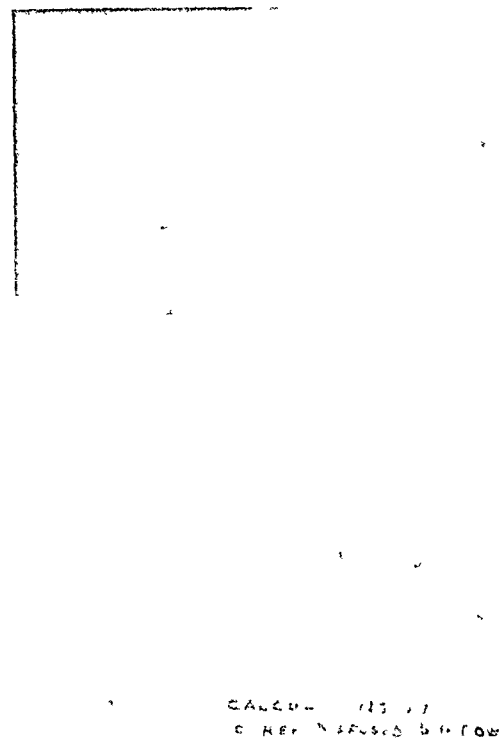

Fig. 3

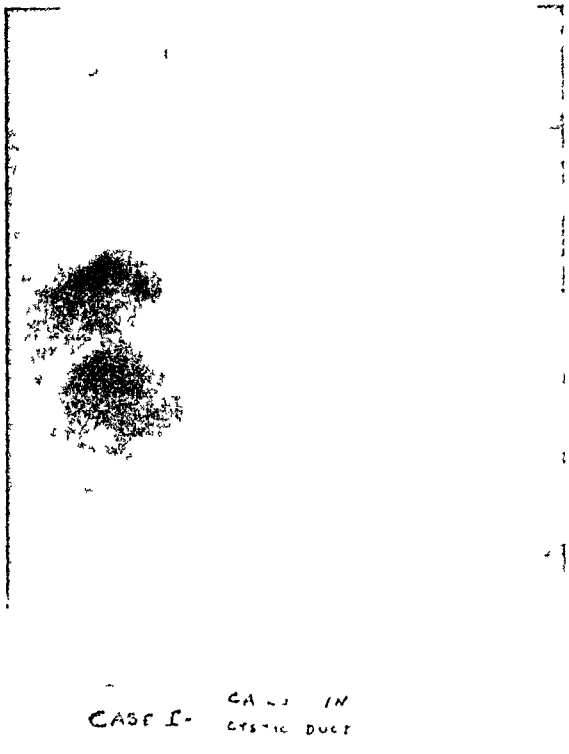

Fig. 2

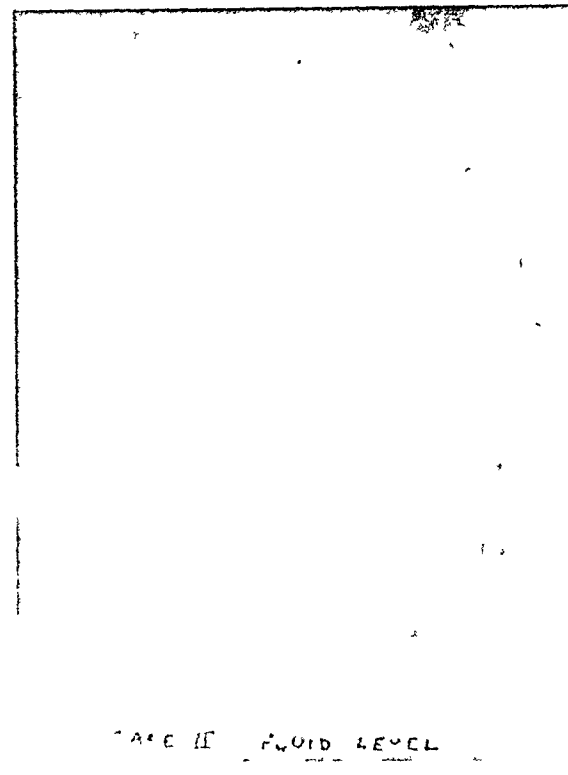

Fig. 4

make one suspicious of this "milk of calcium bile." If this shadow diffuses or changes its appearance, in spite of its persistence, one should be doubly aware of such a diagnosis. The finding of a fluid level with a horizontal line is of great significance. The further finding of stones in the cystic duct is likewise of extreme importance.

We therefore add these two cases to the medical literature because: 1. these cases are not infrequent. 2. they produce interesting X-ray shadows. 3. they emphasize the importance of the relationship between the deposit of calcium in the bile and the production of gall stones.

ABSTRACTS

CLINICAL MEDICINE

WILLETT, JOSEPH C., SIGOLOFF, EMANUEL, AND PFAU, CLIFFORD L.

An Institutional Outbreak of Epidemic Jaundice. J. A. M. A., Vol. 106, pp. 1644-1646, May 9, 1936.

An outbreak of jaundice occurring in a novitiate in St. Louis County during October, 1934, was investigated. Of 132 male students, 32 developed the disease. In the majority of cases it was relatively mild, characterized by a slight, initial elevation of temperature, nausea, vomiting, anorexia, abdominal pain, clay colored stools, bile stained urine and jaundice which in most cases varied from a slight yellowish brown to a deep brown tint. In most cases the jaundice appeared between the first and the fourth day, but in four cases it appeared on the seventh and eighth days. In some of the cases the spleen was palpable, while in others it was not.

The clinical picture suggested Weil's disease. To establish this the demonstration of the Leptospera icterohemorrhagiae was attempted. All material from the patient did not reveal the presence of the Leptospera either upon darkfield examination or guinea pig inoculation. Specimens of water from the holy water fonts revealed organisms identical in morphology and motility with the Leptospera, but guinea pig inoculation produced no infection. However, after the sanitary condition of the fonts was improved the epidemic subsided.

BASSLER, ANTHONY.

Intestinal Obstruction Due to Amebiasis. J. A. M. A., June 6, 1936, Vol. 106, pp. 1960-1968.

A man, aged 50, was first seen by a doctor because of abdominal cramps. The case was referred to the author. The history revealed a man who had been in Chicago during the epidemic of amebiasis eight weeks prior to the onset of the aforementioned symptoms. A diagnosis of amebic dysentery was made and treatment begun. Throughout the course of the next two years it was necessary to continue the treatment because of repeated flare-ups. Late in the second year he was operated on for acute intestinal obstruction by a Chicago surgeon who found a firm annular mass in the colon. About two weeks after the operation he passed some blood and pus from the rectum. This material was found to be full of amoeba. Five weeks after operation his wound became inflamed and started to slough. Examination of this material also was positive for amoebae.

Roentgenograms made after the operation revealed the strictured section of the descending colon. He was constantly under observation and treatment for amebiasis during this time. Frequent roentgenograms were also made which revealed that the strictured condition was clearing up.

This is probably a case of complete intestinal obstruction due to amebiasis. This is an exceedingly rare occurrence, especially since the obstruction was in the sigmoid and not in the cecum or ascending colon as is usually the case.

Francis D. Murphy, Milwaukee.

HECK, F. J., AND WALTERS, WALTMAN.

Development of Macrocytic Anemia Following Resection of the Stomach. Proceedings of the Staff Meetings of the Mayo Clinic. Vol. 11, No. 8, Feb. 19, 1936.

A case is presented of a woman aged 48, with a preceding history of biliary disease, who before final operation presented achlorhydria after an Ewald meal, plus a simple microcytic anemia, but who a year following gastric resection for extensive but localized carcinoma of the stomach presented a macrocytic anemia which was regarded as pernicious (Addisonian) anemia. The discussion of this case is of interest because comparatively few instances of pernicious anemia following gastrectomy are on record, even where the gastrectomy has been total. In this case it was about two-thirds. Moynihan had some evidence of 4 such instances following total resection and Hurst collected one or two others. The striking fact is that even after total gastrectomy where the patient has survived for a few years pernicious anemia does not as a rule, but only exceptionally occur, and the same is even truer of cases in which partial gastrectomy has been done. In fact after partial gastrectomy anemia of any kind is rare. The achlorhydria shown to exist before the final operation was detected by the ordinary Ewald meal and not by histamine injection, but it is at least probable that an achylia gastrica existed.

If we assume that achylia gastrica existed before the final operation for cancer of the stomach, then the intermediate problem of the possible relationship between the achylia and the cancer would be solved by certain investigators, such as Bloomfield, by saying that the gastritis associated with achylia was the factor of irritation producing the cancer, and Hurst would be of the same opinion. Then to classify the preoperative simple anemia as "the idiopathic type of hypochromic anemia" or the achlorhydric microcytic anemia of women is scarcely more logical than to regard it as one of the types of simple anemia which accompany early cancer of the stomach. Indeed there is also a macrocytic anemia associated with cancer of the stomach closely resembling pernicious anemia in smear picture with even glossitis but which may be differentiated from Addison's anemia by a usually higher white blood cell count and by the absence of bilirubinemia and spinal cord changes. In this case there is no record of pigment studies or of neurological examination, although the low leukocyte count favors Addison's anemia. It seems to the reviewer most probable that this patient had the potential *makings* of a true Addison's anemia: if Walters had not so

ably removed her unsuspected cancer she would have died of cancer without ever having pernicious anemia: the successful removal of the cancer allowed the pernicious anemia to develop and in fact the operation itself may have been the "precipitating factor" in bringing on the pernicious anemia, just as pyelitis or pneumonia or a severe nerve strain often precipitates this disease in those who are on the edge of it all the time. The authors believe that the patient may have had pernicious anemia the time she was first seen and that as a result of continued hemorrhage a hypochromic anemia developed and was superimposed on the Addison's anemia, with a resulting microcytic smear picture. This however is impossible, because if a patient with a fully developed Addison's anemia has to contend with the added factor of blood loss from hemorrhage the resultant smear picture is still decidedly macrocytic and the only difference is a lower color index and some degree of comparative achromia. The superimposition of hemorrhagic upon pernicious anemia never influences the morphology of the erythrocytes. As the reviewer has shown years ago, Addison's anemia may be suddenly engrafted upon a simple anemia or upon a normal blood and as soon as it is so engrafted, we see first a distortion of the erythrocytes toward the macrocytic type and with anisocytosis even before there is any oligocythemia or even hemoglobinemia.

THOMPSON, J. W., AND SOPER, H. W.

Combined Medical and Surgical Management of Peptic Ulcer: with Emphasis on the Treatment of Hemorrhage. Ann. Int. Med., Vol. 9, No. 8, 1936.

This article is worth careful study, not only because of the unusually wide-angled viewpoint of the authors, but also because certain of their contentions seem challenging in spite of their good results. Perhaps if all clinicians were to adopt some one good logical course of procedure in treatment as they have done, their results might be better than where the technique is permitted to vary too widely with different cases. Their use of a smooth diet, with frequent feedings to the practical exclusion of alkali is as sane as their good results indicate, and the routine use of sedative and belladonna cannot be overemphasized. Egg white in the raw state is given with apparent benefit, but it would seem that this may be due to some physical effect for it has long since been demonstrated that raw egg white is not digested in the human being. It is a pleasure to hear authors make a plea for the careful *medical* treatment of gastric ulcer, in spite of the danger of confusion with cancer: today there is too great a tendency to refer all stomach ulcerations at once for surgery, forgetting, as the authors do not forget, that gastric surgery, except in the most expert hands still carries an alarming mortality. Where medical treatment is used it goes without saying that the most careful check must be kept up by X-ray on the progress or otherwise of the lesion. The persistence of occult blood in the stools is one of the danger signals of malignancy and should result in surgery. Soper has been using evaporated milk in ulcer treatment for some time, one of the reasons being its sterility. The use of the transgastric indwelling nasal catheter of Levin, recommended by the authors in resistent cases of gastric ulcer, for the purpose of placing food directly into the jejunum and thereby offering the stomach a much needed rest seems in their hands to work well, but it still seems questionable if the good results are due to gastric rest or to limitation of gastric secretion. For example what evidence is there that regurgitation from the duodenum is not actually increased by this method and that such increased regurgitation is not the cause of the good results by acid neutralization. And again, while these authors have obtained good results in ulcer bleeding by the use of the indwelling gastric catheter, through which thromboplastic agents are introduced and by which blood is aspirated, what proof is forthcoming that the presence of the catheter does not actually by its own presence induce much unusual peristalsis? Here are two problems deserving early experimental study.

Beaumont S. Cornell, Fort Wayne.

BASSLER, ANTHONY.

Intestinal Obstruction Due to Amebiasis. J. A. M. A., Vol. 106, 28, June 6, 1936.

A case of amebiasis, acquired in Chicago during the well known epidemic of 1933, proved extremely resistent to the repeated use of all the approved antiamebic remedies as evidenced by recurring attacks of diarrhea and malaise, and the case progressed to a complete intestinal obstruction with fecal vomiting and required emergency caecostomy. Few reports have previously been made of amebic stenosis occurring in the sigmoid which proved to be the case here. Under the influence of further strenuous treatment with vioform, chiniofon, and emetin, the obstruction at the rectosigmoid juncture has given every evidence of disappearing, although it was the impression of the surgeon who operated that obstruction was due to a carcinoma. The report of this case is of importance because of the unusual position of the amebic obstruction, and indicates the importance of not assuming that all obstructions in this region are malignant and therefore less amenable to treatment.

VINSON, P. P., AND BUTT, HUGH R.

Esophagitis: A Clinical Study. J. A. M. A., Vol. 106, pp. 994-996, March 21, 1936.

Much has been written about carcinoma and stricture of the esophagus, but nothing about the commonest pathological condition here, esophagitis. In a recent study, it was found that of 3,032 autopsies, 213 cases, or 7.02% of cases showed evidence of esophagitis. In 10.3 per cent of these cases, there were definite clinical symptoms.

The condition occurs most frequently when there is severe vomiting, or after the passage of a stomach tube. It is also associated with pyloric or duodenal stenosis, gall bladder disease, and occasionally appendicitis.

The most frequent symptom is a burning pain in the region of the middle and lower third of the esophagus, much like that occurring in peptic ulcer. The next most frequent symptom is hematemesis. Dysphagia and melena also occur in some cases.

The simplest treatment is prevention. Vomiting should be controlled as much as possible. Ethyl aminobenzoate lozenges dissolved in the mouth may relieve some of the pain. A bland, smooth diet should also be used. Tincture of belladonna, 20 drops every three or four hours, may relieve the spasm. When ulceration occurs, the passage of a bougie may stretch the base of the ulcer and bring about complete healing.

Francis D. Murphy, Milwaukee.

GAY, L. P.

Gastro-Intestinal Allergy — the Leukopenic Index as a Method of Specific Diagnosis of Allergens Causing Peptic Ulcer. J. A. M. A., Vol. 106, pp. 969-976, March 21, 1936.

The introduction of the leukopenic index as a method of allergic diagnosis is due to the work of Vaughn. He observed that allergens caused a leukopenia in individuals sensitive to a certain allergen and a rise in the leukocytes in individuals not sensitive to that certain allergen. This type of diagnosis has been used in asthma, allergic headache, hypersensitive rhinitis and gastro-intestinal allergies.

This is the report of the treatment of six unselected ulcer cases treated on the premise that peptic ulcer is an allergic manifestation. In three of the six cases there was an allergic history. It was noticed that wheat and milk were definite allergens in all the cases, and egg in 50 per cent of the cases. In these cases skin tests were of little or no value because the clinical reactions of some of the allergens are of the cumulative type. The use of the leukopenic index is the method which was used in determining the allergens.

It was found that an immediate leukopenia was indicative of an aller-

gen, and a leukopenia of slight degree followed by a hyperleukocytosis was of the same significance. It was also found that those foods which produced a leukopenia produced an achlorhydria, and vice versa.

The conclusion was reached that complete relief of peptic ulcer symptoms by a diet that is compatible with the leukopenic index; that relief of pain with conventional methods was due to a state of antianaphylaxis; and that the pain of peptic ulcer was due to a localized anaphylactic spasm.

Francis D. Murphy, Milwaukee.

WALKER, HARRY.

The Etiology of Abdominal Pain in Diabetic Acidosis. Ann. Int. Med., IX, 1178, March, 1936.

The importance of making a correct differential diagnosis, thus avoiding the danger of emergency surgical operations on patients on the verge of diabetic coma, on the one hand, and the seriousness of a delay too long of an operation in diabetics that demand emergency surgery is stressed in the rather small group of patients in which it is difficult or impossible to determine whether or not there is an intra-abdominal surgical lesion present or whether the symptom complex is one entirely due to acidosis. A case is reported to illustrate the difficulty referred to. A diabetic of two years duration was on a weighed diet and a fixed dosage of 60 units of Insulin daily. For 24 hours preceding admission to a hospital an insufficient amount of Insulin was taken. During the following night nausea and vomiting occurred, with the ingestion of large amounts of water. After midnight the patient experienced a sudden attack of sharp pain in the epigastrium, which increased in severity, soon extending over the entire abdomen and radiating to the chest as high as the suprasternal notch. The pain was increased by deep inspiration. The nausea and vomiting, together with the pain, continued, all increasing in severity. During the night an additional 40 units of Insulin was given without any appreciable effect either on the vomiting or the pain. On admission to the hospital the following afternoon a blood sugar of 444 was found, with a plasma CO_2 combining power of 20.2 volumes per cent. With the administration of 50 units of Insulin hypodermically and 1000 c.c. of normal saline by the vein the abdominal pain disappeared completely in three-quarters of an hour and the abdomen became soft.

Attention is called to the infrequency of reports of similar cases, but the observations of McKittrick are quoted. These are (1) Patients that have been studied with operations and no surgical lesion found suggested before the operation a wide-spread abdominal manifestation as the cause of the suspected abdominal pathological process. (2) In diabetic coma vomiting usually precedes the pain, while in pre-coma cases with surgical complications the pain usually precedes the vomiting. (3) When appropriate therapy is applied, signs and symptoms due to acidosis clear promptly, while those of surgical conditions usually progress. The various possibilities as to the cause of the pain are discussed. Dilatation of the stomach is dismissed with the statement that it is common knowledge that gastric dilatation does not produce a true spasm of the abdominal muscle, and that while it does produce discomfort, rarely if ever does agonizing pain result. Hepatic engorgement was also suggested as an explanation, which scarcely seemed to be an adequate reason, since engorgement of the liver as seen clinically, rarely if ever produces a syndrome comparable to that under discussion. Dehydration fails to explain all the facts except that it is an early finding in many precoma cases, the majority of whom certainly present no similar abdominal signs or symptoms, and when dehydration is found in other clinical conditions such signs and symptoms are not observed. In the case reported it would scarcely seem that acidosis be the cause of the pain since acidosis persisted after the pain subsided. It is further suggested that the Insulin was scarcely the sole factor in controlling the symptoms, since a blood sugar of 380 was found after the symptoms had entirely disappeared.

The condition described by Edsall called heat cramp is discussed and attention invited to the fact that this condition is apparently in some way associated with chloride deficiency and that the administration of salt solution not only promptly controls the symptoms but will prevent them. The further emphasis on the possibility of the case reported having something to do with chloride deficiency is refernce to the condition known as "gastric tetany," which is associated with pyloric obstruction and characterized by vomiting and not only abdominal pain but also pain in any group of muscles that are vigorously exercised. As an explanation of abdominal pain in acidosis it is suggested that the chain of events producing the abdominal symptoms probably develops in the order of improper fat oxidation, acidosis development, nausea and vomiting, the depletion of body chloride because of loss of hydrochloric acid, the exercise of the abdominal muscles as the result of the vomiting, hence the pain and hence the relief offered by the administration of sodium chloride solution intravenously. It is admitted that these are merely postulates in this case because no blood chloride determinations were made, but it is suggested that such determinations might not have been a true index to the total body chloride, as plasma chloride may remain normal while the chloride content of the body as a whole may be markedly reduced.

Virgil E. Simpson, Louisville.

GAUSS, HARRY.

The Interrelationship of Gastro-intestinal and Renal Disease. Ann. Int. Med., IX, 1373, April, 1936.

Attention is invited to a relatively small group of cases in which a differentiation between diseases of the kidney and diseases of the gastro-intestinal tract are difficult. The anatomic, neurologic and metabolic relationships between these systems is offered as an explanation of reference of symptoms from one system to the other. The juxtaposition of the kidney to the liver, the duodenum, the hepatic flexure of the colon, the stomach, the spleen, the pancreas and descending colon are offered as reasons for the anatomical relationship.

The nerve supply of both these systems contains autonomic fibers of both vagal and sympathetic types and which have passed for the most part through the celiac plexus. The balance that is normally maintained as to the proportion of certain substances which are excreted in the stools or in the urine is offered as some explanation for the metabolic relationship. No adequate explanation is offered for the exact mechanism involved in these interrelationships that conceal the secret of functional disturbances set up in one system as a result of a diseased process located in the other. These reports are given to illustrate examples of renal disease that presented essentially gastrointestinal symptoms in the author's experience. The discussion closes with the following postulate. 1. The renal and gastro-intestinal systems are related anatomically through their juxtaposition and their ligamentous attachments and neurologically through their common innervation. 2. The following renal disorders have been reported as being common sources of gastro-intestinal symptoms: stricture of the ureter, hydronephrosis, movable kidney, pyelitis, stone. 3. In these conditions examination of the urine may reveal no definite abnormality and therefore be of no aid in diagnosis. 4. Physical examination may be helpful in eliciting characteristic pain or tenderness on palpation of the kidneys or ureters where they cross the pelvic brim, or at the lower ends within the broad ligaments. 5. A definite diagnosis can usually be established by means of ureteral catheterization and urograms.

Virgil E. Simpson, Louisville.

LEARY, TIMOTHY.

1. Atherosclerosis—Special Consideration of Aortic Lesions Archives of Pathology, 21:4, p. 459, April, 1936.

The author concludes from a carefully conducted study of human material obtained at autopsy that all the lesions of aortic atherosclerosis, save early mucoid changes in the intima, are due to the presence of cholesterol. The lesions are primarily intimal and depend for their nutrition upon imbibition through the endothelium. Variations in the structure and appearance of the lesions depend upon the age of the subject and of the lesions themselves. In youth atherosclerosis of the coronary arteries is marked by an increase of subendothelial connective tissue. It is loose textured, possesses no collagen, and is associated with small groups of lipoid cells (lipophages). In the fourth and fifth decades of life collagen formation takes place and results in the production of true scar tissue. In old age lipoid cells accumulate in masses with scant fibrous tissue, and because of failing nutrition necrosis takes place with the formation of atheromatous abscesses. Occlusion of the vessel lumen in youth is due to thrombosis following an acute fibrinous necrosis in the subendothelial layer which extends to the endothelium. In old age occlusion is due to the rupture of an atheromatous abscess into the lumen.

In youth the young fibroblasts metabolize the lipoid and, without an accompanying formation of collagen, minimal scarring takes place. As age advances, cholesterol metabolism within the lipoid cells is slowed, collagen is formed and heavier scar tissue is produced. With failing nutrition through the scar tissue the deeper layers necrose and secondary atheromatous abscesses are formed. In old age cholesterol metabolism ceases, lipoid cells accumulate in masses, nutrition to the area fails, and a primary atheromatous abscess results. The lesion in the ascending arch of the aorta does not follow this rule. Cholesterol metabolism continues unabated in this part of the vessel and the connective tissue formed remains as in youth, which results in minimal scar formation. Calcification arises in connection with necrobiasis or after necrosis has developed and marks the sites formerly occupied by living tissue. Factors, such as hypercholesteremia, thyroid secretion and iodine, age, stress, infection and injury, and toxic factors are discussed, but are held to be factors which influence only the deposit of cholesterol within the artery wall. The nutrition of the lesion within the wall the author believes to be wholly by imbibition from the blood stream through the endothelium. He denies to the vaso vasorum any influence in the process. The paper is profusely illustrated with beautifully prepared microphotographs.

In the second paper the author reviews the criticisms of experimental evidence pointing to cholesterol deposition as being the cause of atherosclerosis in man and reiterates the evidence of its being the only etiological agent at work. These arguments need not be summarized in this review. In the reviewer's opinion the whole question of the etiology of human atherosclerosis remains much as it was before. The cause or causes remain obscure and are probably varied in nature.

WATSON, W. L., AND BANCROFT, F. W.

Hypertrophic Cricopharyngeal Stenosis. S. G. O., Vol. 62, No. 3, pp. 621-624, March, 1936.

The authors report in considerable detail a case of a middle aged woman who presented a benign tumor of the cricopharyngeus muscle due to hypertrophy and degeneration of its fibers together with intracellular edema. The syndrome of which the patient complained caused the authors to diagnose upper esophageal obstruction due to a parathyroid tumor or an atypical thyroid tumor.

At operation the condition was thought to be an inoperable neoplasm. The tumor was sectioned longitudinally down to the mucosa, in much the same manner as was described by Rammstedt in relation to the hypertrophic pyloric sphincter, and a segment of tissue removed.

The post-operative course was stormy incidentally, but the patient recovered completely and is now well.

Eight figures accompany the article.

Nelson M. Percy, Chicago.

OCHSNER, A., GAGE, M., AND HOSOI, K.

Treatment of Peptic Ulcer Based on Physiological Principles. S. G. O., Vol. 62, No. 2-A, pp. 257-274, Feb. 15, 1936.

The authors point out a group of factors in proper sequence and combination as a possible cause of chronic peptic ulceration. They are divided into the uncontrollable group and the controllable group. The former group of factors which in reality are predisposing causes are: (1) tissue susceptibility and (2) constitution predisposition. They represent inherent qualities of the organism and are neither alterable or controllable. The latter group of factors, which may be called precipitating factors, are controllable and amenable to treatment. They are hypersecretion and hyperacidity, focal infection and gastric trauma.

From a series of shunting experiments the author concludes that hypersecretion and hyperacidity are the most important precipitating factors. Gastric trauma is probably the least important of them. Hypersecretion is best controlled by establishment of a normal pyloric function, the avoidance of certain activities which increase gastric acidity and secretion—smoking, especially of cigarettes, ingestion of alcohol and condiments. Neutralization of the gastric acidity is best accomplished by frequent small feedings. Calcium carbonate is the best alkalic for that purpose.

All foci of infection must be removed. Only a bland diet containing no roughage should be allowed.

The surgical treatment of peptic ulcer consists largely of the treatment of complications, such as mechanical obstruction, perforation, repeated hemorrhages, and danger of malignant change.

Gastro-enterostomy is the operation of choice in cases of pyloric obstruction with hypoacidity. It should not be done in cases with marked hyperacidity because of the increased susceptibility of the jejunal mucosa to the acid gastric chyme. In those cases gastro-duodenostomy is preferable. The chronic calloused ulcer in the stomach which does not readily respond to medical treatment should be operated upon and radical resection done.

Ten figures and a large bibliography accompany the article.

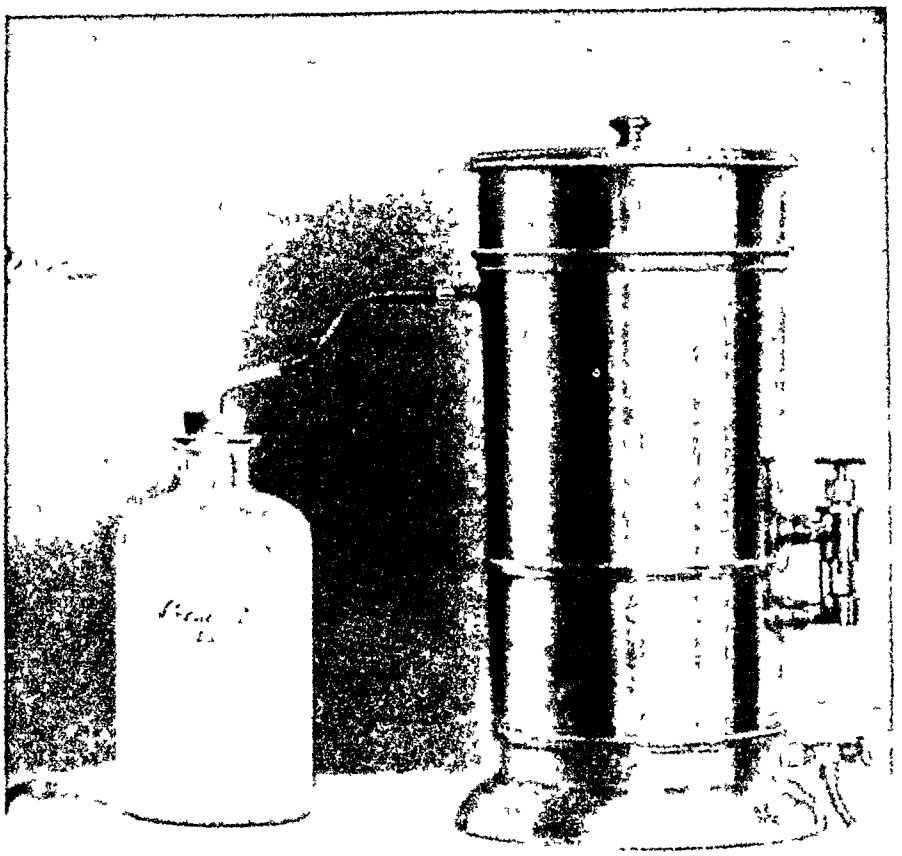
SHALLOW, T. A.

Combined One Stage Closed Method for the Treatment of Pharyngeal Diverticula. S. G. O., Vol. 62, No. 3, pp. 624-633, March, 1936.

As a matter of definition and for the sake of clarity and the advancement of our knowledge of pharyngeal diverticula, the author points out that there are no recorded cases of true pulsion diverticula of the esophagus. The reported cases of diverticula of the esophagus are traction diverticula; all reported pulsion diverticula have been pharyngeal in origin. In support of this view the work of Killian, Mognihan and Jamison is cited. The anatomical work of Killian and Jamison showed a small area of weakness in the pharyngeal wall. That area is a "slit between the pars fundi-formis of the cricopharyngeus muscle and the upper circular fibers of the esophagus. In this slit the recurrent nerve passes through to divide into the anterior and posterior branches." A branch of the inferior thyroid artery and vein and a bundle of lymphatic vessels passes through this biatus. The presence of the recurrent laryngeal nerve in this area explains the symptom of hoarseness which was present in nine of the authors cases. The presence of a larger resistant artery there may explain the occasional double diverticula seen. A diverticulum can arise from any portion of the pharynx which is perforated by a branch of the inferior thyroid artery. The most common areas are: Most fre-



ANNOUNCING the *Creamalin* AUTOMATIC for the TREATMENT of PEPTIC ULCER

The Creamalin Automatic Drip Control now makes a simple routine of the continuous drip treatment of peptic ulcer with colloidal cream of aluminum hydroxide (Creamalin). •• The continuous acid adsorption method apparently represented, on the basis of results reported, a superior therapy in peptic ulcer. Its application was limited, however, because of difficulties encountered in attempting to effectively administer the neutralizing agent as a continuous drip. The Creamalin Automatic Drip Control has entirely overcome these limiting factors and the gastroenterologists now have at their disposal an apparatus that permits a routine institution of this treatment. •• **THE CONTINUOUS DRIP METHOD** Winkelstein[1] first reported on the continuous neutralization method. Woldman and Rowland[2] later reported on a continuous neutralization method that utilized an adsorptive agent. Cream of colloidal aluminum hydroxide (Creamalin) is especially suitable as a neutralizing agent, as one volume will combine with 14 to 25 times its own volume of tenth normal hydrochloric acid by physical fixation without any dangers of alkalosis and without toxic effects of any kind. •• Woldman and Rowland, summarizing their experience, reported that by this method symptomatic relief is usually prompt, and x-ray evidence shows that an ulcer niche may completely disappear in seven days. A constant achlorhydria is produced as evidenced by frequent day and night sampling. The method is entirely compatible with any type of dietetic treatment. There is very little discomfort, and functional rest of both the secretory and motor function of the stomach may be allowed in larger measure during the period of healing. •• **DESCRIPTION OF THE CREAMALIN AUTOMATIC DRIP CONTROL.** This consists of a cylindrical metal container with three compartments, and a single glass bottle whose outlet is connected by a long rubber tube to an indwelling Levin tube. The rate of flow of the drops is controlled by a sight

Gastric ulcer on the lesser curvature at the beginning of treatment.

DRIP CONTROL
by the CONTINUOUS DRIP METHOD

Seven days later: Ulcer deformity is entirely gone.

valve and remains constant wherever set. The apparatus is compact, sturdy, automatic, trouble-free, and requires a minimum of attention. No special skill is required, and it is easy for a doctor or nurse to learn to operate it. ••**WHAT IS CREAMALIN?** Creamalin is a specially prepared colloidal cream of aluminum hydroxide. The technic employed in dispersing the colloidal particles yields a product of unusual neutralizing action, one volume combining with at least fourteen times its volume of tenth normal hydrochloric acid in one hour by physical fixation. It is a pearly white, amphoteric, creamy substance. Creamalin has been used orally in the treatment of thousands of cases of peptic ulcer with gratifying results. Creamalin is especially effective in the continuous drip treatment because it possesses the necessary adsorptive action and does not clog. Large dosage can be administered without disturbance to the acid-base balance. It is free from dangers of alkalosis and secondary acid secretions. ••**THE CREAMALIN DRIP TREATMENT.** The usual routine is to hospitalize the patient and administer Creamalin as a continuous drip for a period of seven to ten days. About a pint of Creamalin is administered every 24 hours. The results with this treatment have been satisfactory, especially in the management of bleeding ulcers. ••**WRITE FOR DETAILS** The treatment of peptic ulcer by the continuous drip method with Creamalin utilizing the Creamalin Drip Control merits the clinical consideration of gastroenterologists. Correspondence is invited, relative to purchase or loan of an apparatus, and material for a clinical evaluation of this method.

BILE SALTS

Fairchild

The sodium glycocholate and taurocholate, the salts of conjugated colic acids in their native association as separated from fresh ox gall.

A stable dry powder; uniform in composition; efficient for the well known therapeutic uses of ox-gall—in disorders due to faulty bile functioning.

Bile Salts preferably to be dispensed in capsule by itself, or in combinations in powder.

Offered in powder, ¼ oz., 1 oz. vials; in capsules, each three grains Bile Salts.

Fairchild Bros. & Foster
New York

quently from the commonly described area above the cricophahyngeus muscle; more often on the left side. The next place in the order of frequency in the authors series of cases was the Killian-Jamison area below the cricopharyngeus muscle. The location least frequently found to be the point of origin of these diverticula has been through the lower portion of the inferior constrictor muscle, a site for another branch of the inferior thyroid artery.

The symptoms of pharyngeal diverticulum are difficult and noisy deglutition, vomiting, hoarseness and occasionally a tumor palpable in the neck. The diagnosis is established by X-ray examination or by esophagoscopy.

The prognosis in this condition is much better than it was some years past. The condition is recognized earlier today.

The author is distinctly not in accord with those who advocate the two stage operation because of the probability of mediastinitis following a one stage operation. He is of the opinion that mediastinitis has been a rare complication in recent years. In his series of 76 cases there were 2 deaths, one from uraemia, the other from pneumonia. Pulmonary complications not infrequently follow the operation.

A detailed account of the authors technic is given.

Eight figures and a bibliography accompany the article.

ROSENBLATE, A. J., GOLDSMITH, A. A., AND STRAUSS, A. A.

A Summary of Regional Ileitis. J. A. M. A., Vol. 106, pp. 1779-1780, May 23, 1936.

For the past thirty years a number of granulomatous lesions of the intestine have been mistaken clinically for malignant or appendicial lesions. In 1932 they were described as a regional ileitis, and a year later as a cicatrizing enteritis.

The etiology of the condition is not known, but infection, especially anaerobic, is a possible cause. The pathologic lesion is a proliferation of the somatic cells of the intestinal wall and the hematopoietic cells. The coats of the intestine are edematous and thickened; the mesentery is thickened and the glands hyperplastic. The lumen gradually becomes narrowed because of fibrostenosis. Frequently there is perforation with localization of a mass in the right lower quadrant.

Microscopically, there is an acute, sub-acute or chronic inflammatory reaction with giant and epithelioid cells present.

Clinically, it is characterized by a low-grade fever having periods of normalcy, diarrhea containing mucus and occult blood, anorexia with loss of weight and secondary anemia, dull cramp-like pain in the right lower quadrant, moderate leukocytosis and rapid pulse. Stenosis occurs in the later stages.

X-ray after an opaque meal shows filling defects proximal to the cecum, abnormal contour of the terminal loop of the ileum, and dilatation of the ileac loops just proximal to the lesion.

The treatment is surgical removel of the diseased areas of the intestine with later anastomosis.

An Epidemic of Infectious Diarrhea in the New-Born. J. A. M. A., Vol. 106, pp. 1256-60, April 11, 1936.

Infectious diarrhea is a condition characterized by sudden onset, slight fever, dehydration, and complicated by upper respiratory and middle ear infections. No specific etiological agent has been isolated to account for this syndrome and there is no characteristic pathology in the gastro-intestinal tract.

Epidemics of this syndrome have in the past been reported on two occasions. Within the last year four such

epidemics have been reported in New York City institutions.

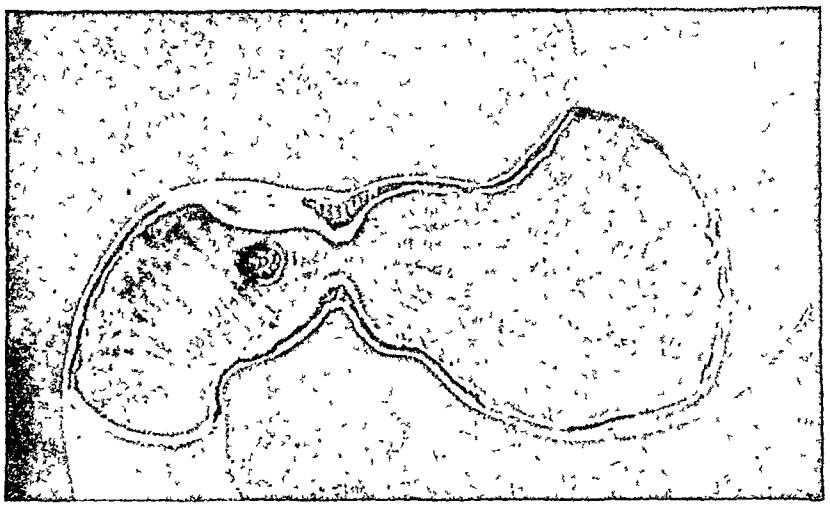
This is the report of an epidemic occurring in Morrisania Hospital in 1935. Of 43 infants in the nursery at the time of onset, 32 developed the disease. Fourteen of these babies died. The morbidity then was 74 per cent and the mortality, 43 per cent.

All the babies were normal, healthy infants previous to the onset. All patients showed a low grade fever never going higher than 103. Diarrhea was present almost from the onset in all cases. There were about six stools per day and all were markedly acid in reaction. Vomiting was present, but only in a few of the cases. The average weight loss in infants who recovered was about eight ounces, was gradual and occurred mainly in the heavier babies. In those who died the loss was about 23 ounces and was accompanied by severe dehydration.

The age of onset varied from two to twenty days. The fact that the onset was so soon after birth indicated a short incubation period.

All the babies affected were isolated, sterile, technique was instituted and all possible sources were cultured for etiologic agents, but none was found. They were treated so as to prevent dehydration and nutritional disturbances. Only in cases of severe vomiting was a period of starvation instituted and in only the most severe cases of vomiting was gastric lavage done. They were given 15 c.c. of protein milk with 3 per cent of carbohydrate alternating with one ounce of 1 per cent saline solution. In addition, 5 min. of epinephrine 1:1000 solution was administered hypodermically every three hours to prevent circulatory collapse.

Necropsy did not show a pathogenic picture in the gastro-intestinal tract to indicate a primary intestinal infection.



Francis D. Murphy, Milwaukee.

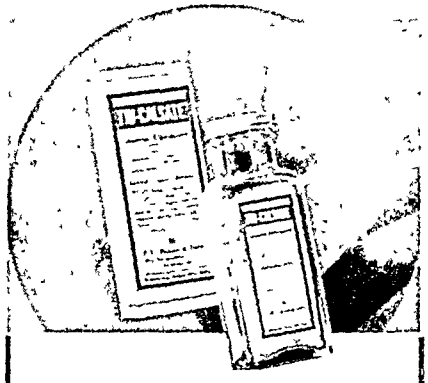
NUTRITION

GOLDZIEHER, MAX A.

Chronic Hypoglycemia. Endocrinology, Vol. 20, No. 1, 1936.

One of the most valuable features of this contribution is a classification of the different types of response obtained to the glucose tolerance test in a large group of chronic hypoglycemics. Goldzieher was able to distinguish 6 rather distinct types of response, as follows: (a) low fasting level, normal rise and return to the fasting level; (b) low fasting level, small rise and return to the fasting level; (c) normal fasting value, no rise and slow consistent below the fasting level (this type was twice as common as any of the other types); (d) low normal fasting value, small rise and substantial terminal drop; (e) low fasting level, sudden high rise, slow return and deep terminal drop (diabetic type); (f) very low fasting level, fairly good rise and early drop to a low point. All these types are found with equal frequency except (c). The actual causes of hypoglycemia are apparently many and of wide spread type, for only about 80% can be referred to hyperinsulinism, and the others are referred to liver damage and extra-pancreatic endocrine factors. Of the types said to be of pancreatic origin, roughly 28% were associated with diseases of the pancreas and the balance regarded as functional hyperinsulinism. The surgical removal of normal pancreatic tissue in patients for the relief of hypoglycemic symptoms proved to be a great clinical disappointment. The reviewer remembers that Banting showed several years ago that a dog could not be rendered diabetic even by the massive injection of glucose so long as even a very small portion of the pancreas remained. It is now practically certain that many hypoglycemics with symptoms of a disagreeable nature owe their trouble to endocrine disturbances other than pancreatic overfunction, just as we believe that many persons with chronically low

DIET-ALKALI *versus* LAROSTIDIN



The Sippy treatment, in its various modifications, is so restrictive as to be irksome to many ulcer patients. They find life a sorry burden.

With the Larostidin treatment there is a minimum of restriction. The diet is rapidly increased to normal, there is no interference with the patient's business or social duties, and there is a remarkable uplift of the spirit that has been smothered by the chronic infirmity.

It has been demonstrated*, moreover, that 70% of the diet-alkali failures make a favorable response to Larostidin. It would seem advisable to start ulcer patients on Larostidin right away

basal metabolic rates owe their biochemical pattern to disturbances other than hypothyroidism. In the true organic hyperinsulinism due to fibroid and adenoma and cancer of the pancreas, relief may be expected from surgical intervention to the same degree as in toxic lesions of the thyroid. The other cases disassociated from organic or 'functional" pancreatic disorder form at present an attractive field of romance. The most common clinical manifestations of hypoglycemia were found to be: abdominal pain, excessive hunger or craving for carbohydrates with coresponding obesity, mild or severe fainting spells and tachycardia. Epileptiform seizures, speech defects and dysmenorrhea were also observed. Probably insufficiency of the pituitary and thyroid may eventually be found to be factors in many of the obscure cases. Lee Martin's paper given at the 1936 meeting of the American Gastro-enterological Association indicated that hypoglycemia is a bewilderingly broad subject in which known factors are yet in the minority.

The Effectiveness of the Sippy Regimen in Neutralizing the Gastric Juice Patients if the Amount of Alkali is Not Varied. Ann. Int. Med., Vol. 9, No. 8, pp. 1070-1077, Feb., 1936, and The Value of a Mixture of Powdered Milk and Alkali for Neutralizing the Gastric Acidity of Patients with Peptic Ulcer, ditto, pp. 1078-1090.

In 46 patients with duodenal ulcer receiving the routine Sippy treatment 30 minute day-long tests of gastric juice samples were made under strict Sippy rules, varying from milk and cream only to "first day," "seventh day" and "fourth week" procedures. The free acidity was adequately controlled in more than one-half the patients and symptoms were entirely abolished in all cases. The data indicate that if the free acidity does not rise above 20 after an alcohol test meal, the patient will obtain adequate control by this method. There seems to be no criteria to determine which patients will be controlled in the large group whose free acidity does go higher than 20 following an alcohol test meal. Calculations suggest that 25 to 50 times more alkali was given than should be necessary theoretically. If a routine treatment is used, one can be assured of complete neutralization only if frequent aspirations are performed.

It was found that 12.5 gm. of a preparation of powdered milk mixed with the usual Sippy powder containing 0.6 gm. of calcium carbonate and 2.0 grams of sodium bicarbonate, and given at intervals of one hour are somewhat more effective in neutralizing the gastric acidity than 90 c.c. of milk and cream and the same powder given in the usual way advised by Sippy.

KLUMPP, THEODORE G.

The Treatment of Pernicious Anemia with Autolyzed Liver Concentrate. J. A. M. A., p. 1245, April 1, 1936.

Reimann in 1931 noticed that the antianemic potency of fresh liver was increased by digestion in normal human gastric juice. Similar results have been reported by various investigators. Herron and McEllroy suggested that a similar enhancement of potency could be obtained by autolysis. This was further influenced by Wills, who found that ordinary yeast was inert, while autlyzed yeast was effective in the treatment of tropical macrocytic anemia.

The authors tried the therapeutic potency of autolyzed liver concentrate—Squibb (N.N.R.) for a period of two years, at the New Haven Hospital. They came to the conclusions that autolyzed liver concentrate is effective in the initial and maintenance treatment of pernicious anemia, that it is more potent than liver extract—Lilly, from the same amounts of liver, that the initial dose to produce maximal effects is that obtained from autolyzed liver concentrate derived from between 150 and 200 of liver, and that the maintenance dose was between one and eight teaspoonsful daily and averaged three teaspoonsful.

VINSON, P. P.

The Treatment of Carcinoma of the Esophagus. S. G. O., Vol. 62, No. 5, pp. 840-842, May, 1936.

The surgical treatment of carcinoma of the esophagus has been disappointing because of the formidable nature of the operation and the highly malignant nature of these tumors. Roentgen Rays and Radium have proved to be of little or no benefit because of the added discomfort they cause the already distressed patient. Electrocoagulation of the mass through the esophagoscope gives promise of being a useful procedure. Intubation of the growth may be accomplished by passing a suitable tube over a previously swallowed silk thread.

Palliative gastrostomy and mechanical dilatation of the stricture are the most widely practiced palliative procedures. If the condition of the patient will not permit gastrostomy, dilatation of the stricture may afford relief for a period of from six to eight weeks. Further dilatations will continue this benefit for an indefinite period.

In the rare cases of esophago-bronchial or esophagotracheal fistula dilata-

tion should not be attempted but recent haemorrhage the author considers, is not a contraindication to dilatation.

ABDOMINAL SURGERY

WOLFSON, W. L., AND ROTHENBERG, R. E.

Acute Noncalculous Cholecystitis. J. A. M. A., Vol. 106, pp. 1978-1980, June 6, 1936.

During the past ten years Wolfson and Rothenberg have operated on 379 cases of acute cholecystitis. Of these, 31 were diagnosed as non-calculous cholecystitis, which diagnosis was confirmed at operation.

In going over these cases it was found that the incidence of acute non-calculous cholecystitis in this series was 8.2 per cent; 58 per cent of the cases occurred in men.

The usual symptoms of gaseous eructations, aversion for fatty foods, and a history of previous attacks is not characteristic of these cases. The disease, however, is characterized by a higher temperature range, greater incidence of chills, greater morbidity and a greater incidence of perforation than other forms of acute cholecystitis. The etiology of the condition is believed to be a hematogenous infection rather than an obstruction in the cystic duct.

Francis D. Murphy, Milwaukee.

KNIGHT, J. C., AND SLOME, DAVID

"Intestinal Strangulation." Brit. Jour. Surg., 23:820-854, April, 1936.

This report deals with the results of a comprehensive experimental study and careful review of the literature. In considering statistical tables, all showing a high mortality in large series of cases of acute intestinal obstruction, the great lesson learned is the extreme urgency of the earliest possible diagnosis and treatment in reducing that mortality. The particular interest in this study was the segregation of those cases of intestinal obstruction without circulatory involvement (due to neoplasms, gall stones, foreign bodies, band compression, etc.) from those of acute intestinal strangulation (due to volvulus intussusception, hernia, etc.) where the essential pathological feature is venous strangulation of the intestine.

Most previous experiments to find the cause of the toxemia developing in both types of cases have been done with occluded but not strangulated loops of intestines. Various factors found to play a part were nervous reflex action, bacterial invasion, distention, dehydration, hypochloremia, and toxic substances developed within the bowel wall or bowel lumen. The striking rapidity of the appearance of collapse in cases of intestinal strangulation would eliminate many of the factors which could well explain the slowly developing symptoms in non-strangulating obstruction—for instance, in strangulation death may take place before there is any appreciable drop in blood chlorides. It is the opinion of the authors that there is produced in the gut wall in severe strangulation a depressor substance. This substance can be demonstrated in the wall and in the peritoneal fluid within an hour and even within the thoracic duct in forty to seventy minutes. It is this substance which accounts for the great fall in blood pressure. Less definite evidence is offered in reproducing the symptoms by injection of this substance in normal animals. Accessory contributory factors that may play a part are the rhythmic alteration in distention and the length of the involved segment of bowel. Due to the fact that release of the strangulated bowel may pour into the circula-

A Nutritious Food of Remarkable Digestibility from Infancy to Old Age

HORLICK'S The Original MALTED MILK

On account of its high food value, easy concentration in small volume when necessary, and its ready digestibility, is useful in the diet for

1. *Infant feeding*
2. *Nursing mothers*
3. *Influenza and pneumonia*
4. *Gastric and Duodenal Ulcer*
5. *Tuberculosis*
6. *Typhoid and other fevers*

J. Duffy Hancock, Louisville.

FRANSEEN, CLIFFORD C.

Les Fistules Cholecysto-coliques Consecutives a la Lithiase. (Douriez-Bataille, Lille, France, 1936).

A 64 page monograph on the subject of cholecystocolic fistula gives a good review of the subject and presents in detail a new case of the author. . He shows that such fistula is practically always the result of gall stones, plus the factor of infection and the commonest mechanism is compressive ulceration by a large calculus. The production of the fistula may be accompanied by a most painful clinical episode or be absolutely unnoticed by the patient. After the formation of the fistula a period of symptom amelioration usually occurs only to be followed by symptoms due to the infection of the bile passages. While a diagnosis might be tentatively made from history and physical examination, reliance must be placed upon the use of an opaque enema to fill the gall bladder. The prognosis is always serious and surgery imperative. Cholecytectomy with suture of the colon gives 75% of cures. The case described by Vorhaus and Rogers in this Journal in April, 1934, is referred to.

Beaumont S. Cornell, Fort Wayne.

FLETCHER, H. N., AND CASTLEDEN, L. S. M.

"Three Cases of Duodenal Diverticulum Removed by Operation." Brit. Jour. Surg., 23:776-786, April, 1936.

Duodenal diverticula are either primary or secondary. The secondary are due to traction of some adjacent inflammatory process and invariably occur in the first part of the duodenum. The primary are more common, and occur generally at the concave inner aspect of the descending limb, only occasionally from the third and fourth portion and never from the first portion of the duodenum. They are thin walled hernia of the duodenal wall, consist of mucosa, submucosa, and possibly a few muscle fibers, are more frequent as age advances, and while usually solitary may be multiple. Perforation and even inflammation of the sac are very rare.

Cases are rather difficult to diagnose symptomatically. The pain is of the deep gnawing type or characterized by heavy discomfort in the epigastrium. The relation of the pain to the intake of food is indefinite. While there are periods of especial distress there is seldom complete disgestive comfort between attacks. The history is often a long one. Gastric flatulence and belching with only incomplete relief is suggestive. Vomiting, if present, may also be ineffectual in giving relief. Some tenderness in the region of the diverticulum was found in all three cases reported. Diagnosis will be established by the X-ray. The treatment in view of the rarity of inflammation and perforation should be non-surgical at first. If the digestive symptoms persist, stasis can be demonstrated in the diverticulum, and other possible causes can be excluded excision should be done. This was not difficult in the three cases under consideration and the results obtained were most satisfactory, absolute relief in the two uncomplicated cases and great improvement in the third where the diverticulum was accompanied by a pyloric adhesion.

J. Duffy Hancock, Louisville.

FRANSEEN, CLIFFORD C.

Gastrostomy Feeding. J. A. M. A., Vol. 106, pp. 1373-1376, April 18, 1936.

The gastrostomy diets used in most hospitals, both large and small, are usually very deficient in the caloric requirement of the patient. They usually consist of milk, eggnogs, malted milk, broth, cream and lactose.

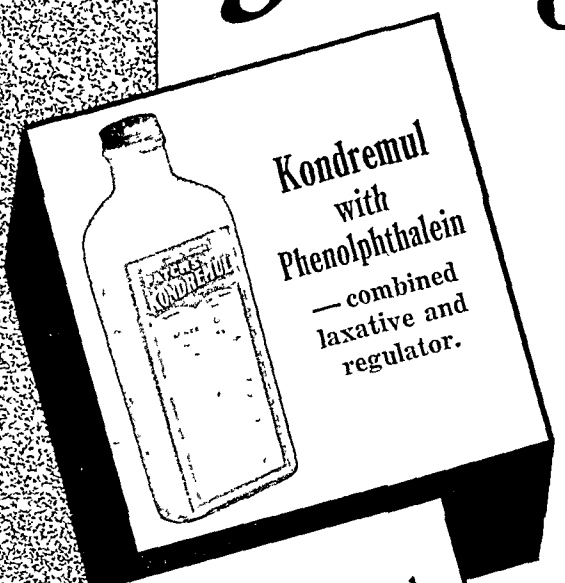
Clinically it has been observed that lactose will cause diarrhea and flatulence, while experimentally it has been observed that from 40 to 50 per cent was lost so far as weight or energy relationship were concerned in the rat.

The diet recommended here consists of seven-and-one-half cups of oatmeal gruel to which corn syrup, melted butter, baby vegetable puree, brewer's yeast powder and table salt have been added, in addition to five poached eggs pushed through a fine strainer.

A special feeding consisting of strained orange, tomato or grapefruit juice, beef scrapings, iron and halibut liver oil is also given.

The feeding schedule is as follows:

1. One-and-one-fourth cupsful of feeding mixture at eight, twelve, two, four, six and eight o'clock.



2. Special feeding at 10:00 A. M.

The first twenty-four hours after operation nothing is given by tube so that the sinus tract will become walled off. Supplementary fluids of 10 per cent glucose or saline are usually given the first three days.

Cereal and vegetables are not given until the full diet is adopted. The quantity of the feedings is gradually increased, until by the eighth day the full diet mixture can be given.

Francis D. Murphy, Milwaukee.

Your Choice OF TREATMENT

Kondremul with Phenolphthalein — combined laxative and regulator.

Kondremul with Cascara — the tonic laxative action of non-bitter cascara added to the soft bulk of Kondremul.

Kondremul Plain — used with safety in children as well as adults.

For every degree of *constipation* encountered in everyday practice, there is a pleasant, smoothly acting type of

KONDREMUL

(Chondrus Emulsion)

The emulsification of mineral oil with Irish Moss (Chondrus Crispus) results in a tough film around each oil globule, and prevents breakdown in the alimentary tract.

Thus, complete admixture with the fecal mass is obtained, giving a soft, moist, bulky stool.

"... we know that in the infant and growing child alkali in excess of acid must be stored."

Growth and Development of the Child, Part III, White House Conference on Child Health and Protection, New York, 1932, p. 213.

BUT— many diets are acid-forming

AS pointed out in the Journal of the American Medical Association (Queries and Minor Notes, 103:701, 1934), "... most high carbohydrate foods of the artificial and refined types are lacking in the basic elements. These basic ions, such as sodium, potassium, and calcium, are necessary for the neutralization and excretion of the various acid waste products of the body. Hence carbohydrates may be implicated in the occurrence of such an acid state by displacing other necessary food products from the dietary."

Ordinary cereals and cereal products, meat, and eggs—all produce an acid ash when burned in the body, yet they form the mainstay of the average diet. Although this preponderance of acid-forming foods is not definitely known to have great significance for the health of normal adults, a number of authorities advocate a basic or alkali-forming diet for children and pregnant women.

INFANCY AND CHILDHOOD. "Alkaline diets are essential for infancy where growth is rapid," declares Shohl. He calculates the need as 10 cc. excess of 0.1 normal base per kilo per day.[1] Babies fed on breast milk stored an excess of base over acid, the range being from 31 to 56 cc. 0.1 N base per day, is the finding of the Committee on Growth and Development of the White House Conference on Child Health.[2] Lippard and Marples observed greater increases in weight of infants receiving basic diets as compared with controls on acid-forming feedings.[3]

PREGNANCY AND LACTATION. Shohl states, "Pregnancy and lactation require additional alkali—a minimum of 150 cc. 0.1 N base per day."[1] Coons and associates, from acid-base balances taken upon normal pregnant women receiving basic diets, determined that the storage of basic substances was even greater than estimated by Shohl. "This may be some indication," they say, "of the magnitude of the maternal needs exclusive of fetus."[4]

As the chief alkali-forming foods are fruits, vegetables, and milk, the ordinary basic diet consisting of these foods is likely to be low in calories and often does not appease hunger. But Pablum—the only base-forming cereal*—offers a way to add muffins, cereal, puddings and similar "filling" foods to the usual basic diet. Pablum, moreover, is richer than ordinary cereals in calcium, phosphorus, iron, and copper and supplies vitamins A, B, and G.

[1-4] *Bibliography on request.* *Mead's Cereal (Pablum in uncooked form) is also base-forming.

MEAD JOHNSON & COMPANY, - - - Evansville, Indiana, U.S.A.

Pablum (Mead's Cereal thoroughly precooked) is a palatable basic cereal consisting of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa leaf, beef bone, brewers' yeast, iron salt and sodium chloride.

Cereal	*Base*	*Acid*
PABLUM	1.8	
Farina		11.0
Oatmeal		12.9
Wheat, whole		11.5
Cornmeal		5.3
Barley		10.1
Rice		8.1

SECTION I—*Clinical Medicine: Diseases of Digestion*

A Classification of Gastro-Duodenal Ulcers on the Basis of Their Etiology*

By

SAMUEL C. ROBINSON, M.D.
CHICAGO, ILLINOIS

THE progress of science in the past has, in a great measure, been aided by classification. This has involved the gathering together of a large mass of data followed by the orderly grouping of kindred facts into separate divisions. It was natural that the early groupings in any single branch of science were large and inclusive in their content. But knowledge is not a static thing nor should the earlier made classifications, based on incomplete knowledge, remain static. In the light of further development and discovery, it is often necessary to break down the material into smaller sub-divisions and to shift some data from one group to another where they are later seen more logically to belong. This process of regrouping and reclassifying, of adding and subtracting until the kinship of each division becomes more definite and clear, contributes greatly to the general understanding of the subject. In all fields this process continues if we are willing to view each new development with objectivity and decline to cling to older classifications simply because they were the original ones or through our misguided attempts to do honor to their worthy protagonists.

Even in the face of newer knowledge and continuous changes in our classifications and theories, it is surprising how many of the outworn interpretations cling to the literature. It is difficult to dislodge them because repeated acceptance by great, though now deceased, authorities in their respective fields lends such prestige to these interpretations that the newer man with less weight of authority to his writing scarcely dares even to challenge them. The fact that in the earlier hypotheses there is often a kernel of truth, though this be encrusted with many irrelevant facts, makes it more difficult to get the whole subject reopened for critical consideration. This situation is most true in the field of medicine which is as yet the least exact of all the biological sciences; the field of gastro-enterology is no exception (1).

Let us consider the mere matter of nomenclature in gastro-duodenal disease.

The very term "peptic" is in itself a misnomer. The term arose years ago when it was thought that all ulcers were located in the stomach. It was therefore natural that the term "peptic" should be used to designate those ulcers. It was short and referred to those erosions originating in the areas of peptic cells. The term had an added connotation of a digestive process and gave implications of etiological significance. A "peptic" ulcer was one that occurred in the mucosa of the stomach lined by pepsin-secreting cells and was supposed to be the result of a process of self-digestion of an enzymic nature. Soon after the discovery of the Roentgen ray it was revealed that most of the ulcers that were supposed to be in the stomach were in reality located in the duodenum. The clinical picture of the two ulcers was the same and it is easy to understand why they were grouped together. Even now with a clearer understanding of these disease entities, differentiation is difficult. The term "gastric" is used interchangeably with "duodenal" and only the keen clinician possessing a well grounded understanding of the history and physical findings and a familiarity with the anthropometric differences of the two types is able to make the differential diagnosis successfully (2). So it is easy to see how these two differently situated ulcers were considered as one, and gastric in location.

Fifty to one hundred years ago the autopsy was the main source of histopathology and its relationship to clinical findings. And it is a well known fact, substantiated by pathologists generally today as well as in Virchow's time, that the incidence of gastric ulcers in autopsy material is greatest, whereas clinically the duodenal type of ulcer outnumbers the gastric about ten to one (3, 4). The X-ray gave this subject a tremendous impetus and revealed to the amazement of the older clinician that what was formerly considered a peptic or gastric lesion was in reality a Brunner's or duodenal lesion in the great majority of cases. But the name stuck to this very day to confuse us and give false implications of its site and etiology, for most ulcers are not peptic in their location nor are they caused by self-digestive enzymic action. "Brunner's ulcers" would be more appropriate but the same objection holds here, namely attention is focussed on the nature of the cell, in which the ulcer develops, which in itself has no relationship to the etiology of the disease, and further many ulcers are gastric in location.

However the duodenal and gastric ulcers do have these two important facts in common: First, embryologically the duodenum and stomach arose from the same *anlage* in the gastro-intestinal tube (the duodenum is in reality more a part of the stomach than it

*From the Department of Medicine, Woodlawn Hospital, Chicago, Illinois.
Submitted March 23, 1936.

is of the intestine), (5) and second, that portion of the gastro-intestinal tract where most ulcers develop, namely, the lesser curvature and the duodenum, receives the bulk of the nerve supply.

From the foregoing it would seem wise to drop from usage the term "peptic" in connection with gastro-intestinal ulceration.

ETIOLOGICAL BASIS OF CLASSIFICATION

Clinical versus Pathological. The classification, presented in this paper is made chiefly on a clinical and etiological basis rather than on a pathological one. Ulcers produced by the identical cause may show a great variety of pathological changes and infinite gradations of them, depending upon their age, chronicity, complications, etc. Ulcers of different groups may present about the same histopathology but as clinicians we are more interested in their classification *on an etiological and physiological basis than in the* end microscopic slide which often ignores these factors. Always in the past we have allowed the pathologist to dominate our thinking in the elucidation of disease. We had to square with his interpretation of dead tissue before we could proceed. This has applied to brain, heart, kidney, endocrine system, especially the thyroid, pancreas, to the gastro-intestinal system, and other viscera.

Internists especially interested in unfolding the emotional factors behind many organic diseases in these systems resent this restricting influence of the pathologist. His inability to show histopathological change in organs that we have seen to have positive clinical evidence of altered function and structural change merely speaks for the limitations in his field. We might quote a pertinent paragraph from Bentley and Cowdry's book "The Problems of Mental Disorder" (6). "Suppose that some physicist tomorrow invents a microscope with much greater useful magnification. At once abnormality may be seen where none was previously visible. But why confine ourselves to the microscope? Certainly there are other ways of recording abnormality of the human organism besides visual observation of fixed and sectioned tissue. For example, the spectroscope may show that a certain type of sugar is found in the urine of an athlete before a contest. This is an observation which may be recorded photographically; it is a phenomenon which can be shown to occur regularly; by chemical methods the sugar may be estimated quantitatively. The average histopathologist, nevertheless, will strenously maintain that there is no organic pathology in this anxious athlete and that the disease is 'merely functional.' What the histopathologist really means is that after an autopsy in this athlete no lesion would be visible in stained section of tissue, with a microscope of the type used in 1931." As physicians we must accumulate the clinical evidence that proves the relationship of psychic trauma to somatic disease. We may then hope that the physiologist and pathologist may set to work and reveal the *modus operandi* of the mechanism involved. In doing so the physiologist will have to abandon his laboratory animal. It would be well that some physiologists be made part of the "Department of Medicine" to catch up with what seems to be already proved by the internist. We must not subscribe to the statement that "In the history of medical research one finds over and over again that progress in the knowledge of the pathogenesis of a disease is made only after the disease can be reproduced in laboratory animals" (20). In the writer's opinion this can not be demonstrated for the following diseases: chronic gastro-duodenal ulcer, irritable colon, ulcerative colitis, thyrotoxicosis, neuro-circulatory asthenia, many degenerative diseases, etc. We must rely increasingly upon *human physiology* as Sir Thomas Lewis has urged so eloquently in the last few years. In the future we shall advance our knowledge of visceral function and pathological physiology chiefly through clinical observation.

Many clinicians today stand ready to give up the relationship of the pancreas to diabetes because the pathologist cannot find sufficient destructive evidence in the islands of Langerhans. This is gross submission to an illogical approach and shows the crushing *hold the cellular theory of disease has on us clinicians.* Can the pathologist tell us from a cross section of the nerve the number of impulses that are relayed to the cells in those islands? Can the pathologist tell us from the microscopic picture which cell in the island secreted one unit of insulin or portion thereof and which ten times that amount? Can he tell us much about the interplay of hormones? Can the pathologist tell us from the examination of ten specimens of human stomachs which one secreted 10%—20%—40% —or 80% of free hydrochloric acid? Which secreted a minimum, moderate and maximum amount of pepsin? Which were rich or poor in the intrinsic factor of pernicious anemia? Which of the stomachs, samples of which he holds in his hand and enjoys the privilege of seeing, feeling, dissecting, staining and subjecting to any chemical test, I repeat, which of these stomachs were hypertonic in life, hypermotile, which only moderately so and which exhibited atonia or excessive reverse peristalsis? Which showed, clinically, hypersensitiveness to emotional disturbances and which were calloused to them? Which of the stomachs were subject to altered autonomic control to produce vascular spasm, thrombosis and ulceration? When the pathologists can answer these questions they may be able to nullify clinical observations, but not until then.

These altered physiological manifestations of the gastro-intestinal tract constitute the earliest signs and symptoms of the sickness and distress for which seventy-five per cent of our patients see us. But the pathologist can as yet throw little or no light on the subject. The future may have a different story to tell, but until then we must, as clinicians, record our observations meticulously, make our deductions and advance our hypotheses for the etiology of disease and its rational therapy even in the face of the pathologist's ridicule (6). At a recent meeting one pathologist commenting on a paper dealing with the relationship of emotions to hypertension, said to the great amusement of the audience, "as pathologists we have as yet not found the seat of emotions."* Shall we shut our eyes to the obvious nervous instability in so many patients which causes pathological physiology and structural change manifested in nearly every

*In the opinion of many physiologists the seat of emotions has been found. The Diencephalon (hypothalamus)—"is the visceral component of emotional reaction and the sympathetic nervous system is under its control." (42)

organ merely because the pathologist has not as yet been able to locate its source? This is indeed worship of a false idol! We should like to stress the point that no attempt is being made to minimize the tremendous importance of pathology in the field of clinical medicine. Attention is being drawn to its limitations today especially in the field of emotions and bodily changes. We are glad to note that some pathologists subscribe to this viewpoint and that their number is increasing.

Inasmuch as our ultimate goal as physicians is the treatment of disease and this cannot well be attempted without an adequate knowledge of its cause, it seems desirable to formulate disease classifications from the etiological standpoint. The following classification of gastro-duodenal ulceration is made on this basis. It is not presented with any idea of finality, for we have seen before the need for constantly re-evaluating in the light of scientific advance, any classifications made. It is, however, presented as the most logical approach in the light of our present frontier of knowledge. Future explorations in the field may modify the classification here presented.

CLASSIFICATION OF GASTRO-DUODENAL ULCERATION

I. DIRECT
- a. Traumatic
  - 1. Internal
  - 2. External
- b. Chemical
- c. Malignant
- d. Infections
  - 1. Tuberculosis
  - 2. Syphilis

II. INDIRECT
- a. Psychogenic (common chronic ulcer; "Peptic" ulcer)
- b. Hemorrhagic erosions—caused by:
  - 1. Nephritis, with or without arteriosclerosis
  - 2. Acute and chronic infectious diseases
  - 3. Debilitating and degenerative diseases, arteriosclerosis, atherosclerosis, amyloidosis, etc.
  - 4. Post-mortem changes
  - 5. Vascular erosions due to cirrhosis of the liver, or any obstruction to gastric vessels—such as gall bladder disease, carcinoma, etc.
- c. Burns
- d. Brain Trauma—Especially to regions about the hypothalamus—tumors, inflammation, surgery
- e. Follicular ulcer
- f. Melena neonatorum

DIRECT ULCERS

The two major divisions of gastro-duodenal ulcers into Direct and Indirect makes clear the general lines of etiology. The Direct group of ulcers includes those that have their origin in the wall of the stomach and duodenum. No systemic factor is responsible for the lesions. Their etiology is to be found in the malignant, traumatic and chemical destruction of the wall itself where the process is initiated. This entire group constitutes but a small portion of all gastro-duodenal ulcers and emphasizes again that the greatest cause of these lesions comes from outside these structures just as we have learned that emesis and stomach disorders are in a great percentage of cases extragastric in origin.

a. Traumatic ulcers. The ulcers that follow internal and external trauma constitute a very small percentage of the Direct Ulcers. They are very acute and short lived and have no resemblance or relationship to the chronic ulcer.

Traumatic ulcers caused by the intake of sharp particles are very rare. Coarse food may cause a temporary break in the mucosa of the stomach but these heal very rapidly. Pins, tacks, glass or other sharp edged objects cause larger and deeper breaks but these, too, heal rapidly, the most classic example being the tack swallower in a side show of a circus. X-ray showed twenty-eight tacks throughout the gastro-intestinal tract with some in the stomach but no ulcers.

We have learned that if large portions of the mucous membrane and considerable submucosal structure of the stomach of animals are removed, chronic ulcer does not form. It does not matter how much acidity is present or even if acidity is added. The course is the same, namely, the ulcer heals rapidly, new mucous membrane bridging the defect.

The same is true in man. "Wounds of the human stomach made by surgeons heal rapidly" (7). Bullet wounds of the stomach, as the army physicians have learned so well during the World War, heal without producing a chronic ulcer (8). All of this evidence would tend to prove the reparative powers of the stomach, its ability to heal small and large abrasions and the fact that hydrochloric acid and pepsin act in no wise as deterrents to the healing process (9).

The injury to the stomach lining or submucosal structures from an external blow does not differ materially from a surgical injury or a bullet wound. There is very little in the line of destruction that a physical blow would accomplish that could not be duplicated by a bullet. There might be some undermining of layers such as the muscularis or mucosa, but it is difficult to see why this particular damage would be more conducive to the production of a chronic ulcer than any anatomical damage produced by a bullet. It might delay healing and cause some hypertonicity and hypersecretion but seldom if ever a chronic ulcer. Nearly all parenchymatous tissue manifests the same ability quickly to arrest any inflammatory or destructive process and even to lay down its particular new cells. This of course takes place in the special medium of the damaged tissue whether it be an acid, alkali, bile or enzymic solution (9). This is part of a simple law of evolution, namely, that highly specialized cells adapt themselves to their particular media. Surgical removal of pieces of liver, uterus, kidney, pancreas, and bowel is followed by quick healing usually by first intention unless complicated by infection. Off hand one would think that hydrochloric acid, pepsin, bile, enzymic solution from the pancreas, putrefactive material from the bowel and rectum would not be ideal solutions in which to bathe healing wounds with their delicate fibroblasts and mitotic cells. But wounds heal in all these media and often very rapidly.

Crohn (10) cites several patients who developed chronic ulcers following external traumata. The list

is small and only after a thorough search of the domestic and foreign literature is even this small number obtained. This alone speaks for the rarity of the condition which would strike one as unusual considering how common the chronic ulcer syndrome is in the general population namely, about 5% to 10%. As stated above, most ulcers caused by external trauma heal rapidly. If we do find in the very rare instance, that a gastro-duodenal lesion following external trauma persists and becomes a chronic ulcer in spite of the natural reparative tendencies of the organ, we must infer that there is some individual diathesis to the disease. External trauma to about 5% to 10% of the population who have a latent constitutional defect of their lesser curvature and duodenum might well produce a lesion here, not because of the trauma alone but rather due to the shock, the spasm and thrombosis that follow in susceptible individuals. It is interesting to note that nearly all of the cases cited in Crohn's paper are *along the lesser curvature* and duodenum where over 95% of the chronic ulcers *naturally* occur. The literature holds far *more* records of the sudden onset of chronic ulcer in patients who were in accidents *without* any trauma occurring to the stomach. Accidents, not entailing any bodily injury whatsoever, may precipitate a chronic ulcer. The shock alone in these latter cases is sufficient to initiate an emotional upset leading to the spasm of the vessels and ultimately to ulceration. One cannot overlook the factor of shock and the resulting disturbance of the emotional equilibrium in any violent blow to the abdomen. The best of us would have some emotional reaction and to those more sensitive, the accident might serve as a "trigger-release" setting loose an outflow of stimuli that could not be controlled before actual ulceration would be produced. To ascribe the formation of a chronic ulcer to trauma alone is to ignore the vast accumulated evidence of constitutional and personality uniqueness of the ulcer-type of patient which a blow cannot produce (2, 11). If we could find even a small series of cases in which a blow to the abdomen produced an ulcer along the *posterior* aspect of the stomach, where the psychogenic ulcer seldom if ever occurs, and in a short and stocky negress which type and race are practically free from the disease, we would say that the experimental evidence looked strong.

The absence of any gastro-intestinal disturbance prior to trauma does not exclude, entirely, the existence of ulcer. In some instances ulcers and scars in the gastro-duodenum are found in the operating room and at autopsy without any former history of dyspepsia. Nor does the absence of a dyspeptic history exclude the ulcer type of individual who as yet has escaped gastro-intestinal manifestations of his disease but is waiting for some "oppositional environment" to come along and permit dyspeptic response. This is our interpretation of most of the chronic ulcers following external trauma. In other words, trauma *per se* cannot produce a chronic ulcer.

Diaphragmatic hernia has been shown to produce gastric ulcer (36). This would seem to be due to external trauma and is therefore placed under this heading.

b. Chemical Ulcers. Strong alkalies or acids may produce ulceration but more often extensive scarring. The diet of some Ethiopian tribesmen, consisting of capsicum and peppers, produces ulceration of the stomach. Alcohol has been shown to produce lesions of the stomach. These ulcers are all very acute and subside when the offending irritant is removed.

c. Malignant Ulcers. The malignant ulcer is classified as belonging to the Direct Group rather than as being secondary to any chronic ulcer. It is presumed that there has been an hereditary transmission of a nest of cells in the stomach wall. At some predetermined time they abandon their dormant hybernating state and break out as a malignant growth. This is an independent process and has no relationship to any other diseased states of the stomach. The proof that malignancy takes place in any benign ulcer has not been established (12). The evidence is mostly against any such conclusion. Most ulcers occur in the duodenum, most malignancies in the stomach seldom in the duodenum. The site of most malignancies is along the posterior aspect of the stomach and the immediate prepyloric region (13), few chronic benign ulcers occur in these locations; they occur mostly along the lesser curvature. Malignancy is associated with low acidity or its entire absence; ulcer with its increase. The build of the ulcer patient is long and thin, that of the malignant patient may be of any type. There is also a difference in the age groupings at the time of onset in the two diseases. Carcinoma cuts across the lines of race, sex, age groups, build and personality types (48). Those who claim the relationship are on the defensive and must produce the proof. It is significant that those who argue for the malignant transformation of chronic ulcer have already reduced their recent estimates from 12% to 3%.*

d. Infections. Ulcers of the gastro-duodenum caused by bacteria are due in most instances to tuberculosis or syphilis. The clinical course of the ulcer itself may parallel the systemic disease. There may be some argument in favor of classifying these ulcers under the *Indirect* group inasmuch as the portal of entry of the organism probably is elsewhere than in the mucous membrane of the duodenum or stomach. The production of the ulcer, however, is due entirely to the intramural growth of the bacteria and the subsequent destruction of tissue to produce the erosion. While the bacteria may be secondary to some original focus the erosion is primary and independent of any systemic factor.

II. INDIRECT ULCERS

Most ulcers of the gastro-duodenum come under this classification. Causes from outside these structures, such as psychic, toxic, bacterial and so forth act to effect changes in the different layers of the stomach and duodenum. Systemic diseases of diverse kinds may, as an associated disturbance, leave their imprint on the vulnerable gastro-intestinal tract. The ulcers in this group are secondary to some other diseased process. They may be the major manifestation of a systemic condition as the chronic ulcer is, or most *incidental* to it as are the hemorrhagic erosions.

a. Psychogenic Ulcer. This group alone is in the author's opinion the cause of about 95% of all gastro-

*We wish to emphasize the extreme importance of this conclusion. There would be a great saving in morbidity and mortality if that thesis were more generally taught instead of the prevalent one that urges surgical intervention on any patient over 40 who has a benign ulcer.

duodenal lesions. It is the common chronic ulcer generally designated as "peptic." Earlier in this paper reasons were given for discontinuing the use of this word. Instead the word "psychogenic" seems more correct etiologically speaking.

While there may be some difference of opinion as to whether the *psyche* alone can produce a gastro-duodenal ulcer, an ever-increasing number of clinicians agree that it plays some role. Dr. Ivy (14) says, "I have yet to meet a clinician of extensive experience who denies that sustained anxiety is a factor in determining the chronicity and recurrence of "peptic" ulcer in many cases." The literature is fairly replete with articles by outstanding men stressing the importance of the emotional factor in chronic ulcer. Current literature of the last few years contains more articles than during any previous period (15, 16, 17, 18, 11, 20). The following men have in their recent writings given expression to this view: Alvarez (37, 43), Alexander (19), Cannon (27, 28), Crohn (29, 46), Cushing (30), Draper (26, 2), Durante (22), Fulton (25, 44), Hartman (21), Mayo (24), Moschowitz (17), Russ (23), Rivers (38), etc.

The term "psychogenic" is gaining in popularity, and it has a specific connotation. The term chronic* if used alone is not descriptive, conveys no definite understanding of the type meant and is therefore insufficient. The looseness of the word "chronic" allows for the running together and confusion of ulcers belonging in separate groups. It is for this reason that classification in this field is essential. It would disentangle one type from another and assign each to its proper grouping in bold relief.

Let us see how applicable this becomes for the psychogenic ulcer. If we studied this single type of ulcer and recorded the findings peculiar to it we might gain a clear picture of the disease. A brief summary of such findings would be as follows: The history is one of years' standing and is unusually constant and classic. Distress comes one to two hours after meals and is relieved by food. There are seasonal remissions and exacerbations. As yet the psychogenic ulcer has not been found in the lower animals, rarely in the *pure* Negro, occurs most frequently in the long thin white person, at least ninety-five out of one hundred; occurs in the male about eight to twelve times as frequently as in the female; occurs in certain personality types with a fairly definite pattern of emotional instability. It is associated with hypermotility of the gastro-duodenum, hyperchlohydria, and hyperacidity. The location of the ulcer is along the lesser curvature of the stomach and the first portion of the duodenum. The pathology shows a clean cut-out ulcer with adjoining mucosa normal,* (31) with thrombosis, ischemia and induration. The kidney function is normal, the blood pressure is normal and the blood picture is normal (11). There is a growing recognition that the foregoing constitute the "irreducible minimum" of the findings in the largest percentage of psychogenic ulcers, in which case the elucidation of this disease becomes greatly simplified.

Any theory of etiology would have to fit these divergent and widely separated findings into a complete mosaic. Contrariwise, the presence of so many different findings common to this unique disease limits the number of possible hypotheses that can be advanced. For instance, the theory of focal infection could not stand up very long to explain all the facts surrounding the disease. The *pure* Negro is as subject to focal infection as the white race if not more so, yet the race on the whole rarely develops the disease. Likewise the "lateral" type individual should have as many infected teeth, tonsils, prostate, gall bladder, appendix, endocardium, dura, et cetera, as the long thin type yet he seldom develops an ulcer. The female ought to have as many bacteria floating in her blood stream seeking a place upon which to alight as the male yet only one of her sex develops an ulcer to ten of the males. We need not go any further to show that the application of logic alone in this one matter of focal infection* would settle the question in the negative without much ado if most gastro-enterologists accepted the findings in connection with the gastro-duodenal ulcer as stated above.

But a large percentage of the findings unfortunately are not generally accepted and in a certain measure because of errors in classification. Let us consider ways in which the findings of a psychogenic ulcer could be confused easily with some other type and thus *vitiate the value of the true picture in each case.*

b. Hemorrhagic Erosions. These erosions occur in connection with many acute or chronic diseases, purpura, malignancy, nephritis, leukemia, gall bladder disease, and even as post-mortem changes. These are the ulcers that most often are confused with the psychogenic type. The guess is ventured that the statistical findings in some series of the common chronic ulcer are made rich by what is seen in this group of hemorrhagic erosions.

Nephritis is responsible for the largest number of these gastro-intestinal erosions. Francine (45) found forty-two gastro-intestinal ulcers in a large autopsy series and seventeen of these were due to nephritis. These ulcers may occur in the esophogus, stomach, small and large bowel, but more frequently in the stomach.

There may be hemorrhage from *any* mucous membrane. There may be bleeding from the urinary bladder and from the mucous membrane of the upper respiratory tract, gums, pharynx and massive alveolar hemorrhage. In many instances the bleeding is due to diapedesis and no destruction of mucous membrane is visible. Dr. Jaffe reports one such case of fatal gastric hemorrhage and at autopsy no defect in the mucous membrane of the stomach could be found. But where the ulceration does take place it is fairly distinctive. The ulcers are very shallow, show no evidence of induration either at the margins or at the base, *i.e. the* underlying structures seem unchanged. The whole wall is soft to the touch, the process appears of recent origin, days or weeks, as if a very thin

*The acute and chronic ulcer are identical in etiology and differ only in most instances in the time-interval of observation. Out of a hundred supposedly acute gastro-intestinal ulcers, if observed over a five year period, approximately 90% of them would show exacerbations of the ulcer syndrome if not of the actual ulceration. In this paper, therefore, the term "chronic" will be used to include the so-called acute group.

*"In my gastroscopic observations, in at least one-half of the gastric ulcers, I found the surrounding *mucosa normal*. No infection or swelling was visible."

*This does not constitute the entire argument against the *rôle* of focal infection as a major factor in the etiology of gastro-duodenal ulceration. The reasons presented have been limited to these few relevant facts to demonstrate the value of classification and the orderly grouping of findings in unravelling the mysteries of this disease.
